In presenting this book the authors believe that its title sufficiently indicates its purpose and scope. It may be well, however, to add a few words on certain features to which it is desired to call special attention.

In order to provide for the needs of both class room and laboratory the book has been divided into two parts, the first part presenting the theoretical side of the subject and the second part its experimental side. By this means it is believed that a closer correlation of laboratory and class work may be secured, and also that the student will obtain a more effective knowledge of the subject and the book prove a more valuable addition to his professional library.

The mechanics of materials, as ordinarily presented, differs essentially from the mathematical theory of elasticity, in that the former is concerned with the development of special rules applicable to the structural forms in common use, whereas the latter deals with the general relations between stress and deformation in an elastic solid, irrespective of its size or form. While special rules may be sufficient in most cases, the student should have some knowledge, at least, of the general fundamental principles upon which they are based, in order that he may be in a position to treat new problems as they arise. With this in mind, the first two chapters have been devoted to a general discussion of the relations between stress and deformation, and to the demonstration of certain elementary theorems which serve as a basis for the special rules of calculation subsequently developed.

In the analytical treatment of the subject the aim has been to give a systematic development, combining rigor with simplicity. In accordance with this purpose such fundamental ideas as Hooke's law and Bernoulli's assumption have been given in detail, and special emphasis placed on the limitations to their validity. It may also be noted that the moment of inertia is presented as the shape factor in
the mechanics of materials, and that a graphical method is given for
determining the gravity axis and moment of inertia of any plane area.

In the treatment of curved pieces, such as hooks, links, and springs, a
simple graphical method of analysis is developed, which, it is believed,
is the only rigorous and at the same time simple general treatment
of the subject which has yet appeared in any American text-book.

Many of the subjects treated in Part I, such as influence numbers,
the principle of least work, arched ribs, etc., are not found in other
American text-books of this grade. Such subjects have been uni-
formly reserved for the latter part of each chapter, and are preceded
by a footnote to the effect that they may be omitted if desired. By
this means it is thought that the book may also be easily made avail-
able for architectural students, or for others of whom little math-
ematical preparation is required, and who have only a brief time
allotted for the study of the subject.

In Part II the chief feature is the increase in scope over similar
works, as indicated by the inclusion of separate chapters on reënhanced
concrete, timber, rope, cable, wire, and belting.

In preparing this part the chief aim has been to guide the stu-
dent in his selection and use of the vast amount of information
now available on the physical properties of materials. With this in
mind, only essentials have been given, and care has been taken that
the book should not be overloaded with information seldom used.
The problems have been so chosen as to illustrate the text, and also
insure a thorough knowledge on the part of the student of that por-
tion of the subject under consideration. A special effort has been
made to present the subject in a clear and concise form, so as to
make it easily understood by a junior in engineering work, and, at
the same time, to render it interesting and inspiring as well.

As a consistent and uniform notation is an essential feature of any
scientific work, care has been taken that each letter or symbol shall
have, so far as possible, but one signification. For convenience of
reference a tabulated statement of the notation is given immediately
after the table of contents, with references to those articles in which
each symbol is defined or used in a representative manner.

THE AUTHORS

CONTENTS

PART I—MECHANICS OF MATERIALS

CHAPTER I

ELASTIC PROPERTIES OF MATERIALS

CHAPTER II

FUNDAMENTAL RELATIONS BETWEEN STRESS AND DEFORMATION

CHAPTER III

ANALYSIS OF STRESS IN BEAMS

Relation between shear and bending moment. — Designing of beams.
— Distribution of shear over rectangular cross section. — Distribution of shear over circular cross section. — Cases in which shear is of especial importance. — Oblique loading. — Eccentric loading. — Antipole and antipolar. — Core section. — Application to concrete and masonry construction. — Calculation of pure bending strain by means of the core section. — Stress trajectories. — Materials which do not conform to Hooke’s law

CHAPTER IV
FLEXURE OF BEAMS

CHAPTER V
COLUMNS AND STRUTS

Nature of compressive stress. — Euler’s theory of long columns.
— Columns with one or both ends fixed. — Independent proof of formulas for fixed ends. — Modification of Euler’s formula. — Rankine’s formula. — Values of the empirical constants in Rankine’s formula. — Johnson’s parabolic formula. — Johnson’s straight-line formula. — Cooper’s modification of Johnson’s straight-line formula.
— Beams of considerable depth

CHAPTER VI
TORSION

— Helical springs
CONTENTS

CHAPTER VII

SPHERES AND CYLINDERS UNDER UNIFORM PRESSURE

- Hoop stress.
- Hoop tension in hollow sphere.
- Hoop tension in hollow circular cylinder.
- Longitudinal stress in hollow circular cylinder.
- Differential equation of elastic curve for circular cylinder.
- Crushing strength of hollow circular cylinder.
- Thick cylinders; Lamé’s formulas.
- Maximum stress in thick cylinder under uniform internal pressure.
- Bursting pressure for thick cylinder.
- Maximum stress in thick cylinder under uniform external pressure.
- Thick cylinders built up of concentric tubes . . . . . . . 122-134

CHAPTER VIII

FLAT PLATES

- Theory of flat plates.
- Maximum stress in homogeneous circular plate under uniform load.
- Maximum stress in homogeneous circular plate under concentrated load.
- Dangerous section of elliptical plate.
- Maximum stress in homogeneous elliptical plate under uniform load.
- Maximum stress in homogeneous square plate under uniform load.
- Maximum stress in homogeneous rectangular plate under uniform load.
- Non-homogeneous plates; concrete-steel floor panels . . . . . . . . . . . . . . . . . . . 135-144

CHAPTER IX

CURVED PIECES: HOOKS, LINKS, AND SPRINGS

- Erroneous analysis of hooks and links.
- Bending strain on curved piece.
- Simplification of formula for unit stress.
- Curved piece of rectangular cross section.
- Effect of sharp curvature on bending strength.
- Maximum moment in circular piece.
- Plane spiral springs . . . . . . . . . . . . . . . . . . . 145-158

CHAPTER X

ARCHES AND ARCHED RIBS

I. Graphical Analysis of Forces

- Composition of forces.
- Equilibrium polygon.
- Application of equilibrium polygon to determining reactions.
- Equilibrium polygon through two given points.
- Equilibrium polygon through three
given points. — Application of equilibrium polygon to calculation of stresses. — Relation of equilibrium polygon to bending moment diagram . . . . . . . . . . . . . 159-168

II. CONCRETE AND MASONRY ARCHES

III. ARCHED RIBS

Stress in arched ribs. — Three-hinged arched rib. — Two-hinged arched rib. — Second method of calculating the pole distance. — Graphical determination of the linear arch. — Temperature stresses in two-hinged arched rib. — Continuous arched rib fixed at both ends. — Graphical determination of the linear arch for continuous arched rib. — Temperature stresses in continuous arched rib . . 182-194

CHAPTER XI

FOUNDATIONS AND RETAINING WALLS

PART II — PHYSICAL PROPERTIES OF MATERIALS

CHAPTER XII

IRON AND STEEL

Introductory. — Tension tests. — Compression tests. — Flexure tests. — Method of holding tension specimens. — Behavior of iron and steel in tension. — Effect of overstrain on wrought iron and mild steel. — Relative strength of large and small test pieces. — Strength

CHAPTER XIII
LIME, CEMENT, AND CONCRETE

CHAPTER XIV
REÉNFORCED CONCRETE

Object of reéenforcement. — Corrosion of the metal reéenforcement. — Adhesion of the concrete to the reéenforcement. — Area of the metal reéenforcement. — Position of the neutral axis in reéenforced concrete beams. — Flexure of reéenforced concrete beams. — Linear variation of stress. — Other uses of reéenforced concrete . . . . . . . . . . . 263-271

CHAPTER XV
BRICK AND BUILDING STONE

CONTENTS

CHAPTER XVI

TIMBER

Structure of timber. — Annual rings. — Heartwood and sapwood.
— Effect of moisture. — Strength of timber. — Compression tests.
— Flexure tests. — Shearing tests. — Indentation tests. — Tension tests.
— European tests of timber. — Tests made for the tenth census.
Tests made by the Bureau of Forestry. — Recent work of the Bureau
of Forestry . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 282–297

CHAPTER XVII

ROPE, WIRE, AND BELTING

Wire. — Wire rope. — Testing of rope, wire, and belting. — Strength
of wire rope. — Strength of manila rope. — Strength of leather and
rubber belting . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 298–305

INDEX . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 309–314

- \( \eta \): Correction coefficient, 65.
- \( \theta \): Angle of twist, 92.
- \( \kappa \): Ratio between tensile and shearing strength, 67.
- \( \lambda \): Arbitrary integer, 26, 82.
- \( \mu \): Constant, 95.
- \( \nu \): Empirical constant, 11, 89.
- \( \pi \): Ratio of circumference to diameter.
- \( \rho \): Radius of curvature, 66, 108.
- \( \sigma \): Empirical constant, 11, 89.
- \( \Sigma \): Symbol of summation, 25.
- \( \phi \): Angle of shear, 33, 92.
- \( \omega \): Angle of repose, 169.
STRENGTH OF MATERIALS

Part I

MECHANICS OF MATERIALS
PART I

MECHANICS OF MATERIALS

CHAPTER I

ELASTIC PROPERTIES OF MATERIALS

1. Introductory. In mechanics all bodies considered are assumed to be perfectly rigid; that is to say, it is assumed that no matter what system of forces acts on a body, the distance between any two points of the body remains unchanged.

It has been found by experiment, however, that the behavior of natural bodies does not verify this assumption. Thus experiment shows that when a body formed of any substance whatever is acted upon by external forces it changes its shape more or less, and that when this change of shape becomes sufficiently great the body breaks. It has also been found that the amount of change in shape necessary to cause rupture depends on the material of which the body is made. For instance, a piece of vulcanized rubber will stretch about eight times its own length before breaking, while if a piece of steel is stretched until it breaks, the elongation preceding rupture is only from $\frac{1}{10}$ to $\frac{1}{5}$ of its original length.

2. Subject-matter of the strength of materials. Since the assumption of rigidity upon which mechanics is based cannot be extended to natural bodies, mathematical analysis alone is not sufficient to determine the strength of any given structure. A knowledge of the physical properties peculiar to the material of which the structure is made is also essential.

The subject-matter of the strength of materials, therefore, consists of two parts. First, a mathematical theory of the relation between the external forces which act on a body and its resultant change of shape, by means of which the direction and intensity of the forces acting at any point of the body may be calculated; and, second, an
experimental determination of the physical properties, such as strength and elasticity, of the various materials used in construction.

Although it is convenient to divide the subject in this way, it must be understood that the two parts are, in reality, inseparable; for the mathematical discussion involves physical constants which can be found only by experiment, while, on the other hand, experiment alone is powerless to determine the form which should be given to construction members in order to secure efficiency of design with economy of material.

3. Stress, strain, and deformation. Whenever an external force acts on a body it creates a resisting force within the body. This, in fact, is simply another way of stating Newton's third law of motion, that to every action there exists a reaction equal in magnitude and opposite in direction. This internal resistance is due to innumerable small forces of attraction exerted between the molecules of the body, called "molecular forces," or stresses. A body subjected to the action of stress is said to be strained, and the resulting change in shape is called the deformation.

For example, suppose a copper wire 40 in. long supports a weight of 10 lb. and is stretched by this weight so that its length becomes 40.1 in. Then the sum of the stresses acting on any cross section of the wire is 10 lb., and the effect of this stress is to strain the wire until its deformation, or increase in length, is .1 in.

4. Tension, compression, and shear. In order to determine the relation between the stresses at any point in a solid body, only a small portion of the body is considered at a time, say an infinitesimal cube. This small cube is then assumed to act like a rigid body, and the relations between the stresses which act on it are determined by means of the conditions of equilibrium deduced in mechanics.

By the principle of the resolution of forces, the stresses acting on any face of such an elementary cube can be analyzed into two components, one perpendicular to the face of the cube and the other lying in the plane of the face. That component of the stress which is perpendicular to the face of the cube is called the normal stress. If the normal stress pulls on the cube, and thus tends to increase its dimensions, it is called tension; if it pushes on the cube, and thus tends to decrease its dimensions, it is called compression. Tension is indicated by the sign + and compression by the sign −.
That component of the stress which lies in the plane of the face
tends to slide this face past the adjoining portion of the body, and
for this reason is called the shear, since its action resembles that of a
pair of scissors or shears.

5. Unit stress. If the total stress acting on any cross section of
a body is divided by the area of the cross section, the result is the
stress per unit of area, or unit stress. In what follows $p$ will be used
to denote the unit normal stress and $q$ to denote the unit shear.
Thus if a bar 2 in. square is stretched by a force of 800 lb., the
unit normal stress is

$$ p = + \frac{800 \text{ lb.}}{4 \text{ in.}^2} = + 200 \text{ lb./in.}^2. $$

If a rod is subjected to tension, it is customary to assume that the
stress is uniformly distributed over any cross section of the rod.
This assumption, however, is only approximately correct; for if two
parallel lines are drawn near the center of a rubber test piece, as $ab$ and $cd$ in Fig. 1, $A$, it
is found that when the test piece is subjected
tension these two lines become convex
toward one another, as indicated in Fig. 1, $B$, showing that the tensile stress is greater near
the edges of the piece than at the center. In
such a case of nonuniform distribution of
stress, the smaller the area considered the
nearer the unit stress approaches its true
value. That is to say, if $\Delta P$ is the stress acting on a small area
$\Delta F$, then, in the notation of the calculus,

$$ p = \lim \frac{\Delta P}{\Delta F} = \frac{dP}{dF}. $$

**Problem 1.** A post 1 ft. in diameter supports a load of one ton.† Assuming
that the stress is uniformly distributed over any cross section, find the unit
normal stress.

**Problem 2.** A shearing force of 50 lb. is uniformly distributed over an area
4 in. square. Find the unit shear.

* For the sake of brevity and clearness all dimensions in this book will be expressed
as above; that is, "lb. per sq. in." will be written "lb./in.²," etc.
† Throughout this book the word "ton" is used to denote the net ton of 2000 lb.
6. **Unit deformation.** If a bar of length \( l \) is subjected to tension or compression, its length is increased or diminished by a certain amount, say \( \Delta l \). The ratio of this change in length to the original length of the bar is called the **unit deformation**, and will be denoted by \( s \). Thus

\[
s = \frac{\Delta l}{l}.
\]

In other words, the unit deformation is the elongation or contraction per unit of length, or the percentage of deformation, and \( s \) is therefore an abstract number.

**Problem 3.** A copper wire 100 ft. long and .025 in. in diameter stretches 2.16 in. when pulled by a force of 15 lb. Find the unit elongation.

**Problem 4.** If the wire in Problem 3 was 250 ft. long, how much would it lengthen under the same pull?

**Problem 5.** A vertical wooden post 30 ft. long and 8 in. square shortens .00374 in. under a load of half a ton. What is its unit contraction?

7. **Strain diagrams.** As mentioned in Article 1, experiment has shown that the effect of the action of external forces upon a body is to produce a change in its shape. If the body returns to its original shape when these external forces are removed it is said to be **elastic**, whereas if it remains deformed it is said to be **plastic**.

For instance, the steel hairspring of a watch is an example of an elastic body, for although it is compressed thousands of times daily it returns each time to its original shape when the compressive force is removed. Wood, iron, glass, and ivory are other examples of elastic substances.

As examples of plastic bodies may be taken such substances as putty, lead, and wet clay, for such materials retain any shape into which they may be pressed.

It has been found by experiment that most of the materials used in engineering are almost perfectly elastic, if the forces acting on them are not too large. That is to say, if the external forces do not surpass a certain limit, the permanent deformation, although not zero, is so small as to be negligible. If, however, the external forces gradually increase, there comes a time when the body no longer regains its original form completely upon removal of the stress, but takes a permanent "set" due to plastic deformation. If the external forces increase beyond this point, the permanent (or plastic)
deformation also increases; or, in other words, the tendency of the body to return to its original form grows less and less until rupture occurs.

For example, suppose that a rod of steel or wrought iron is stretched by a tensile force applied at its ends. Then if the unit tensile forces acting on the rod are plotted as ordinates and the corresponding unit elongations of the rod as abscissas, a curve will be obtained, as shown in Fig. 2.*

Consider the curve for wrought iron obtained in this way. For stresses less than a certain amount, indicated by the ordinate at $A$ in Fig. 2, the deformation is very slight and is proportional to the stress which produces it, so that this portion $OA$ of the strain diagram is a straight line. For stresses above $A$ the deformation increases more rapidly than the stress which produces it, and consequently the strain diagram becomes curved. When the stress reaches a certain point $B$ the material suddenly yields, the deformation increasing to a marked extent without any increase in the stress. Beyond this point the deformation increases with growing rapidity until rupture is about

* Drawn from data given in the *United States Government Reports on Tests of Metals.*
to take place. At this stage of the experiment, indicated by $C$ on the diagram, the material in the neighborhood of the place where rupture is to occur begins to draw out very rapidly, and in consequence the cross section of the piece diminishes at this point until rupture occurs.

Within the portion $OA$ of the strain diagram the stress is proportional to the deformation produced, and the material may be considered to be perfectly elastic. For this reason the point $A$, which is the limit of proportionality of stress to deformation, is called the elastic limit. The point $B$, at which the first signs of weakening occur, is called the yield point.

In commercial testing the tests are usually conducted so hurriedly that the position of the point $A$ is not noted, and consequently the yield point is often called the elastic limit. The yield point, however, is not the true elastic limit, because plastic deformation begins to be manifested before this point is reached, namely, as soon as the stress passes $A$.

At $C$ the tangent to the strain curve is horizontal. Therefore the ordinate at this point indicates the maximum stress preceding rupture, which is called the ultimate strength of the material.

8. Hooke's law and Young's modulus. The fact that within the elastic limit the deformation of a body is proportional to the stress producing it was discovered in 1678 by Robert Hooke, and is therefore known as Hooke's law. It can be stated by saying that the ratio of the unit stress to the unit deformation is a constant; or, expressed as a formula,

$$\frac{P}{s} = E,$$

where $E$ is a constant called the modulus of elasticity. $E$ is also called Young's modulus, from the name of the first scientist who made any practical use of it.

Since $s$ is an abstract number, $E$ has the same dimensions as $p$ and is therefore expressed in lb./in.$^2$. Geometrically $E$ is the slope of the line $OA$ in Fig. 2.

The answers given to the following problems were obtained by using the average values of Young's modulus given in Article 22.

Problem 6. A steel cable 500 ft. long and 1 in. in diameter is pulled by a force of 25 tons. How much does it stretch, and what is its unit elongation?
Problem 7. A copper wire 10 ft. long and .04 in. in diameter is tested and found to stretch .289 in. under a pull of 50 lb. What is the value of Young's modulus for copper deduced from this experiment?

Problem 8. A round cast-iron pillar 18 ft. high and 10 in. in diameter supports a load of 12 tons. How much does it shorten, and what is its unit contraction?

Problem 9. A wrought-iron bar 20 ft. long and 1 in. square is stretched .266 in. What is the force acting on it?

9. Poisson's ratio. It has been found by experiment that when a rod is subjected to tension or compression its transverse dimensions are changed as well as its length. For instance, if a round rod is in tension, it increases in length and decreases in diameter, whereas, if the rod is compressed, it decreases in length and increases in diameter. Experiment has also shown that this lateral contraction or expansion is proportional to the change in length of the bar; that is to say, the ratio between the two is a constant. This constant is denoted by \( \frac{1}{m} \), and is called Poisson's ratio, from the name of its originator.

Poisson's ratio varies somewhat for different materials, but ordinarily lies between \( \frac{1}{3} \) and \( \frac{1}{4} \). Values of this ratio for a number of materials are given in Article 22.

Problem 10. What is the lateral contraction of the bar in Problem 9?

Problem 11. A soft steel cylinder 1 ft. high and 2 in. in diameter bears a weight of 75 tons. How much is its diameter increased?

10. Ultimate strength. From the definition given in Article 7, the ultimate strength of a body is the greatest unit stress it can stand without breaking. In calculating the ultimate strength no account is taken of the lateral contraction or expansion of the body, the ultimate strength being defined as the breaking load divided by the original area of a cross section of the piece before strain. The reason for this arbitrary definition of the ultimate strength is that the actual load on any member of an engineering structure usually lies within the elastic limit of the material, and within this limit the change in area of a cross section of the member is so small that it can be neglected.

Tabulated values of the ultimate strength of various materials in tension, compression, and shear are given in Article 22.
Problem 12. How great a pull can a copper wire .2 in. in diameter stand without breaking?

Problem 13. How large must a square wrought-iron bar be made to stand a pull of 3000 lb.?

Problem 14. A mild steel plate is \( \frac{1}{4} \) in. thick. How wide must it be to stand a pull of 1 ton?

Problem 15. A round wooden post is 6 in. in diameter. How great a load will it bear?

11. Elastic law. Certain substances, notably cast iron, stone, cement, and concrete, do not conform to Hooke's law, in that the deformation is not proportional to the stress which produces it. Consequently, for such substances the strain diagram is nowhere a straight line, but is curved throughout, as shown in the curve for cast iron in Fig. 2. In this case the modulus of elasticity changes from point to point. It is customary, however, to retain the formula

\[ E = \frac{P}{s}, \]

which defines the modulus of elasticity at any point as the slope of the chord joining that point to the origin.

Numerous attempts have been made to determine the equation of the strain curve for various materials which do not conform to Hooke's law, and a corresponding number of formulas, or elastic laws, have been proposed. The one which agrees best with experiment is the exponential law, expressed by the formula

\[ s = \nu p^\sigma, \]

where \( \nu \) and \( \sigma \) are constants determined by experiment. From Bach's experiments the values of \( \nu \) and \( \sigma \) were found to be

for cast iron in tension, \( \nu = \frac{1}{1381709}, \quad \sigma = 1.0663 \);

for cast iron in compression, \( \nu = \frac{1}{1132709}, \quad \sigma = 1.395 \);

the unit stress \( p \) being expressed in atmospheres (1 atm. = 14.7 lb./in\(^2\)).

However, all such elastic laws are at best merely interpolation formulas which are approximately true within the limits of the experiments from which they were obtained. For this reason it is best to carry out all investigations in the strength of materials under the assumption of Hooke's law, and then modify the results by a factor of safety, as explained in Article 21.
12. Classification of materials. Materials ordinarily used in engineering construction may be divided into three classes, — plastic, supple, and elastic.

Plastic materials are characterized by their inability to resist stress without receiving permanent deformation. Examples of such materials are lead, wet clay, mortar before setting, etc.

Supple bodies are characterized by their lack of stiffness. In other words, supple bodies are capable of undergoing large amounts of elastic deformation without receiving any plastic deformation. In this respect plastic and supple bodies exhibit the two extremes of physical behavior. Examples of supple bodies are rubber, copper, rope, cables, textile fabrics, etc.

Elastic bodies comprise all the hard and rigid substances, such as iron, steel, wood, glass, stone, etc. For such bodies the plastic deformation for any stress within the elastic limit is so small as to be negligible; but when the stress surpasses this limit the plastic deformation becomes measurable and gradually increases until rupture occurs. This permanent deformation is the outward manifestation of a change in the molecular arrangement of the body. For a stress within the elastic limit the forces of attraction between the molecules are sufficiently great to hold the molecules in equilibrium; but when the stress surpasses the elastic limit, the molecular forces can no longer maintain equilibrium and a change in the relation between the molecules of the body takes place, which results in the body taking a permanent set.

Rigid bodies have the character of supple bodies when one of their dimensions is very small as compared with the others. An instance of this is the flexibility of an iron or steel wire whose length is very great as compared with its diameter. Furthermore, rigid bodies behave like plastic bodies when their temperature is raised to a certain point. For example, when iron and steel are heated to a cherry redness they become plastic and acquire the property of uniting by contact.

13. Time effect. It has been found by experiment that elastic deformation is manifested simultaneously with the application of a stress, but that plastic deformation does not appear until much later. Thus if a constant load acts for a considerable time, the deformation
gradually increases; and when the load is removed the return of the body to its original configuration is also gradual. This phenomenon of the deformation lagging behind the stress which produces it is called **hysteresis**.

The gradual increase in the deformation under constant stress is also called the **flow** of the material; and the gradual return of the body to its original shape upon removal of the stress is known as **elastic afterwork**. Flow of the material is characteristic of such metals as soft steel and wrought iron, and becomes especially noticeable just before rupture.

**14. Fatigue of metals.** If a stress lies within the elastic limit, it can be removed and repeated as often as desired without causing rupture. If, however, a metal is stressed beyond the elastic limit, and this stress is removed and repeated, or alternates between tension and compression, a sufficient number of times, it will eventually cause rupture. This phenomenon is known as the **fatigue of metals**, and has been made the subject of laborious experiment by Wöhler, Bauschinger, and others. The results of their experiments show that the less the range of variation of stress, the greater the number of repetitions or reversals of stress necessary to produce rupture. Among other results Bauschinger found that for cast iron with an ultimate tensile strength of 64,100 lb./in.\(^2\), the maximum tensile stress which could be removed and repeated indefinitely without causing rupture was 35,300 lb./in.\(^2\); and that the maximum stress which could be alternated indefinitely between tension and compression of equal amounts without causing rupture was 29,100 lb./in.\(^2\). For other kinds of iron and steel Bauschinger obtained similar results, the limit of reversible stress in each case agreeing closely with the elastic limit. From this we conclude that the elastic limit of a material is much more important than its ultimate strength in determining the stability of an engineering structure of which it forms a part.

The fatigue of metals indicates that dislocation of matter begins to be produced as soon as the elastic limit is passed, and continues under the action of relatively small forces. This is confirmed by the well-known fact that if, as the result of a blow, a fissure or crack is started in a piece of glass or cast iron, this fissure will spread without any apparent cause until the piece breaks in two, the only way
of stopping this tendency to spread being by boring a small hole at either end of the fissure.

The explanation of the above is that for stresses within the elastic limit the temperature of the body is not raised, and consequently all the work of deformation is stored up in the body to be given out again in the form of mechanical energy upon removal of the stress. If, however, the elastic limit is surpassed, the friction of the molecules sliding on each other generates a certain amount of heat, and the energy thus transformed into heat is not available for restoring the body to its original configuration.

15. Hardening effects of overstraining. When such materials as iron and steel are stressed beyond the elastic limit, it is found upon removal of the stress that the effect of this overstrain is a hardening of the material, and that this hardening increases indefinitely with time. For example, if a plate of soft steel is cold punched, the material surrounding the hole is severely strained. After an interval of rest the effects of this overstrain is manifested in a hardening of the material which continues to increase for months. If the plate is subsequently stressed, the inability of the portion overstrained to yield with the rest of the plate causes the stress to be concentrated on these portions, and results in a serious weakening of the plate.

Other practical instances of hardening due to overstrain are found in plates subjected to shearing and planing, armor plates pierced by cannon balls, plates and bars rolled, hammered, or bent when cold, wire cold drawn, etc.

16. Fragility. In the solidification of melted bodies different parts are unequally contracted or expanded. This gives rise to internal stresses, or what is called latent molecular action, and puts the body in a state of strain without the application of any external forces. For instance, if a drop of melted glass is allowed to fall into water, the outside of the drop is instantly cooled and consequently contracted, while the inside still remains molten. Since the part within cannot contract while molten, the contraction of the outside causes such large internal stresses that the glass is shattered.

Bodies in which latent molecular action exists have the character of an explosive, in that they are capable of standing a large static stress but are easily broken by a blow, and for this reason they are
called brittle or fragile. The explanation of fragility is that the vibrations caused by a blow are reinforced by the latent internal stresses until rupture ensues.

17. Initial internal stress. In certain bodies, such as cast iron, stone, and cement, a state of internal stress may exist without the application of any external force. This initial internal stress may be the result of deformation caused by previously applied loads, or may be occasioned by temperature changes, as mentioned in the preceding article. The first load applied to such bodies gives them a slight permanent deformation, but under subsequent loads their behavior is completely elastic. The first load, in this case, serves to relieve the strain due to initial internal stress, and consequently the behavior of the body under subsequent loads is normal. A body which is free from internal stress is said to be in a “state of ease,” a term which is due to Professor Karl Pearson.

18. Annealing. The process of annealing metals consists in heating them to a cherry redness and then allowing them to cool slowly. The effect of this process is to relieve any initial internal stress, or stress due to overstrain, and put the material in a state of ease. Hardening due to overstrain is of frequent occurrence in engineering, and the only certain remedy for it is annealing. If this is impracticable, hardening can be practically avoided by substituting boring for punching, sawing for shearing, etc.

19. Temperature stresses. A property especially characteristic of metals is that of expansion with rise of temperature. The proportion of its length which a bar expands when its temperature is raised one degree is called the coefficient of linear expansion, and will be denoted by \( L \). The following table gives the value of \( L \) for one degree Fahrenheit for the substances named.

If a body is fixed to immovable supports so that when the temperature of the body is raised these supports prevent it from expanding,
ELASTIC PROPERTIES OF MATERIALS

13

stresses are produced in the body called temperature stresses. Thus suppose a bar of length \( l \) is rigidly fastened to immovable supports and its temperature is then raised a certain amount. Let \( \Delta l \) be the amount the bar would naturally lengthen under this rise in temperature if left free to move. Then the stress necessary to produce a shortening of this amount is the temperature stress.

If the temperature of the bar is raised \( T \) degrees,

\[
\Delta l = LT,
\]

and consequently

\[
s = \frac{\Delta l}{l} = LT.
\]

Therefore, if \( p \) denotes the unit temperature stress,

\[
p = sE = LT.
\]

The temperature of metals also has a marked influence upon their ultimate strength. Experiments along this line show that at \(-296^\circ\) F. the tensile strengths of iron and steel are about twice as great as at ordinary temperatures.*

**Problem 16.** A wrought-iron bar is 20 ft. long at \( 32^\circ \) F. How long will it be at \( 95^\circ \) F.?

**Problem 17.** A cast-iron pipe 10 ft. long is placed between two heavy walls. What will be the stress in the pipe if the temperature rises \( 25^\circ \) ?

**Problem 18.** Steel railroad rails, each 30 ft. long, are laid at a temperature of \( 40^\circ \) F. What space must be left between them in order that their ends shall just meet at \( 100^\circ \) F.?

**Problem 19.** In the preceding problem, if the rails are laid with their ends in contact, what will be the temperature stress in them at \( 100^\circ \) F.?

**20. Effect of length, diameter, and form of cross section.** When an external force is first applied to a body the internal stress is distributed uniformly throughout the body and, consequently, all parts are equally deformed. When the stress surpasses the elastic limit this is no longer true, and certain portions of the body begin to manifest greater deformation than others. For instance, consider a bar of soft steel under tension. As the stress increases from zero to the elastic limit the bar gradually lengthens and its cross section diminishes, all parts being equally affected. When the stress passes beyond the elastic limit the cross section at some particular point of the bar,

* Everett, C.G.S. System of Units, p. 62.
usually near the center, begins to diminish more rapidly than elsewhere. This contraction of section intensifies the unit stress at this point, and this in turn tends to a still greater reduction of section until finally rupture occurs.

The appearance of a bar subjected to a test of this kind is represented in Fig. 3. The contracted portion, $AB$, of the bar is called the region of striction. The contraction of the section at which rupture occurs is usually considerable; for soft steel its amount is from .4 to .6 of the original area of the bar.

In Article 6 the unit elongation was defined as the ratio of the total elongation to the original length of the bar. It has been found by experiment, however, that the extent of the region of striction depends on the transverse dimensions of the bar and not on its length, the region of striction increasing in extent as the transverse dimensions of the bar increase. Consequently, if two bars are of equivalent cross section but of different lengths, the region of striction will be the same for both, and therefore the unit elongation will appear to be less for the long bar than for the short one. On the other hand, if the two bars are of the same length, but one is thicker than the other, the region of striction will be longer for the thick bar, and therefore the unit elongation of this bar will appear to be greater than for the other.

The form of cross section of test pieces subjected to tensile tests has also an important influence on their elongation and on their ultimate strength. If a sharp change in cross section occurs at any point, nonductile materials, such as cast iron, will break at this section under a smaller unit stress than they could otherwise carry. This is due to a greater intensity of stress at the section where the change in area occurs.
ELASTIC PROPERTIES OF MATERIALS

For ductile materials, such as wrought iron and mild steel, the striction extends over a length six or eight times the width of the piece. Consequently, if the test piece has a form similar to one of those represented in Fig. 4, in which the length $AB$ is less than six or eight times the width of the piece, the flow of the metal is restrained and therefore its ultimate strength is raised. This has an important bearing on the strength of riveted plates subjected to tensile strain. It has been experimentally proved that such plates will stand a greater tension than plates of uniform cross section whose sectional area is equal to the sum of the sectional areas between the rivet holes.

In Article 10 the ultimate strength was defined as the ratio of the maximum stress to the original sectional area of the bar. It is evident from what precedes, therefore, that the unit elongation and the ultimate strength are not absolute quantities, but depend on the form of the test piece and the conditions of the test. For this reason it is absolutely essential that the results of any test be accompanied by an accurate description of the circumstances under which they were obtained. The elastic limit and modulus of elasticity, on the contrary, have an intrinsic value independent of their method of determination, and therefore more accurately define the elastic properties of any material.

The tensile strength of long rods is affected in a way different from any of the preceding. Since no material is perfectly homogeneous, the longer the rod the greater the chance that a flaw will occur in it somewhere. If, then, by numerous tests of short pieces, it has been determined how much a material lacks of being homogeneous, the strength of a rod of this material of any given length can be calculated by means of the theory of probabilities. Such a theory has been worked out by Professor Chaplin* and verified experimentally.

If one dimension of a body is very small compared with the others, as, for example, in long wires or very thin plates, the body

may be permanently deformed by stresses below the elastic limit. The reason for this is that the smallest dimension of such a body is of the same order of magnitude as the deformation of one of the other dimensions, and consequently Hooke's law does not apply in this case.

21. Factor of safety. In order to assure absolute stability to any structure it is clear from what precedes that the actual stresses occurring in the structure must not exceed the elastic limit of the material used.

For many materials, however, it is very difficult to determine the elastic limit, while for other materials for which the determination is easier, such as iron and steel, the elastic limit is subject to large variations in value, and it is impossible to do more than assign wide limits within which it may be expected to lie. For this reason it is customary to judge the quality of a material by its ultimate strength instead of by its elastic limit, and assume a certain fraction of the ultimate strength as the allowable working stress.

The number which expresses the ratio of the ultimate strength to the working stress is called the factor of safety. Thus

\[
\text{Factor of safety} = \frac{\text{ultimate strength}}{\text{working stress}}.
\]

No general and rational method of determining the factor of safety can be given. For, in the first place, formulas deduced from theoretical considerations rest on the assumption that the material considered is perfectly elastic, homogeneous, and isotropic,—an assumption which is never completely fulfilled. Such formulas give, therefore, only an approximate idea of the state of stress within the body.

Moreover, the forms of construction members assumed for purposes of calculation do not exactly correspond to those actually used; also certain conditions are unforeseen, and therefore unprovided for, such as the sinking of foundations, accidental shocks, etc.

In metal constructions rust is another element which tends to reduce their strength, and in timber constructions the same is true of wet and dry rot. Care is usually taken to prevent rust and decay, but the preservative processes used never perfectly accomplish their object.
Besides these elements of uncertainty every construction is attended by its own peculiar circumstances, such as the duration to be given to it, the gravity of an accident, etc., which requires a special determination of the factor of safety.

For all these reasons it is impossible to definitely fix a factor of safety which will fit all cases, and the only guide that can be given as to its choice is to say that it will lie between certain limits. According to Résal,* the factor of safety for iron, steel, and ductile metals should be 4 or 3, and never less than 2½; for heterogeneous materials, such as cast iron, wood, and stone, the factor of safety should lie between 20 and 10, and never be less than the latter.

**Problem 20.** In the United States government tests of rifle-barrel steel it was found that for a certain sample the unit tensile stress at the elastic limit was 71,000 lb./in.², and that the ultimate tensile strength was 118,000 lb./in.². What must the factor of safety be in order to bring the working stress within the elastic limit?

**Problem 21.** In the United States government tests of concrete cubes made of Atlas cement in the proportions of 1 part of sand to 3 of cement and 6 of broken stone, the ultimate compressive strength of one specimen was 883 lb./in.², and of another specimen was 3256 lb./in.². If the working stress is determined from the ultimate strength of the first specimen by using a factor of safety of 5, what factor of safety must be used to determine the same working stress from the other specimen?

**Problem 22.** An elevator cab weighs 3 tons. With a factor of safety of 6 how large must a steel cable be to support the cab?

In the first column of the tables the limiting values of the constants are given, which serves to indicate the wide range of variation to which these so-called constants are subject.

The average values of the constants are tabulated in the second column and agree closely with the values ordinarily given in engineers' handbooks. They are not to be regarded as more correct than the values tabulated in the first column, but are inserted for convenience in solving the problems in this book.

23. Relations between the stress components. In order to determine the relation between the stresses and deformations within an elastic body, it is necessary to make certain assumptions as to the nature of the body and the manner in which the external forces are applied to it.

The first assumption to be made is that the material of which the body is composed is homogeneous; that is to say, that the elastic properties of any two samples taken from different parts of the body are exactly alike. If, moreover, the surface of the body is continuous and the external forces are distributed continuously over this surface, or, in other words, if there are no cracks or other sudden changes of section in the body, and the external forces are distributed over a considerable bearing surface, it follows, in consequence of the above assumptions, that the deformation at any point of the body is a continuous function of the coordinates of that point. In other words, under the above assumptions the deformation at any point of the body differs only infinitesimally from the deformation at a neighboring point.

Since, by Hooke's law, the stress is proportional to the deformation, it follows that the stress is also distributed continuously throughout the body,—that is, that the stress at any point of the
body differs only infinitesimally from the stress at a neighboring point. This is called the law of continuity.

Now consider an infinitesimal cube cut out of an elastic body which is subject to the above assumptions, and let the coördinate axes be taken along three adjacent edges of the cube, as shown in Fig. 6. Then, from the law of continuity, the resultant of the stresses acting on any face of this cube is equal to their sum and is applied at the center of gravity of the face. Consequently, these resultants must all lie in one or other of the three diametral planes drawn through the center of the cube parallel to the coördinate planes. The stresses lying in any one of these planes, say the diametrical plane parallel to $ZOX$, will then be as represented in Fig. 7.

Since the resultant normal stresses on opposite faces of the cube approach equality as the faces of the cube approach coincidence, we may write

$$p_1 = p'_1 \quad \text{and} \quad p_2 = p'_2.$$

For equilibrium against rotation the four shearing stresses must also be of equal intensity, and therefore

$$q_1 = q'_1 = q_2 = q'_2.$$

By considering the other two diametral planes similar relations between the normal and shearing stresses can be established. Consequently, the shearing stresses at any point in an elastic body in planes mutually at right angles are of equal intensity in each of these planes.
24. **Planar strain.** If no stress occurs on one pair of opposite faces of the cube, the stresses on the other faces all lie in one of the diametral planes. This is called the planar condition of strain.

Suppose the Z-axis is drawn in the direction in which no stress occurs, as shown in Fig. 8. Then the stresses all lie in the plane parallel to XOY, and the relation between them is as represented in Fig. 7 of the preceding article.

25. **Stress in different directions.** As an application of planar stress, consider a triangular prism on which no stress occurs in the direction of its length. Let the Z-axis be drawn in the direction in which no stress occurs, and let \( \alpha \) denote the angle which the inclined face of the prism makes with the horizontal, as shown in Fig. 9. Then if \( dF \) denotes the area of the inclined face \( ABCD \), and \( p', q' \) denote the normal and shearing stresses on this face respectively, \( p' \) and \( q' \) can be expressed in terms of \( p_x, p_y \) and \( q \) by means of the conditions of equilibrium. Thus, from \( \Sigma \) hor. comp. = 0,

\[
p'dF \sin \alpha + q'dF \cos \alpha - p_x dF \sin \alpha - q dF \cos \alpha = 0.
\]

Similarly, from \( \Sigma \) vert. comp. = 0,

\[
p'dF \cos \alpha - q'dF \sin \alpha - p_x dF \cos \alpha - q dF \sin \alpha = 0.
\]

Dividing by \( dF \), these equations become

\[
\begin{align*}
p' \sin \alpha + q' \cos \alpha - p_x \sin \alpha - q \cos \alpha &= 0, \\
p' \cos \alpha - q' \sin \alpha - p_x \cos \alpha - q \sin \alpha &= 0.
\end{align*}
\]
Relations between Stress and Deformation 23

Eliminating $q'$,

$$p' = p_x \sin^2 \alpha + p_y \cos^2 \alpha + 2q \sin \alpha \cos \alpha.$$  

From trigonometry,

$$\sin^2 \alpha = \frac{1 - \cos 2\alpha}{2}, \quad \cos^2 \alpha = \frac{1 + \cos 2\alpha}{2}, \quad 2 \sin \alpha \cos \alpha = \sin 2\alpha.$$  

Therefore, by substituting these values,

(2)  

$$p' = \frac{p_x + p_y}{2} \cos 2\alpha + q \sin 2\alpha.$$  

Similarly, by eliminating $p'$ from equations (1),

(3)  

$$q' = \frac{p_x - p_y}{2} \sin 2\alpha + q \cos 2\alpha.$$  

**Problem 23.** At a certain point in a vertical cross section of a beam the unit normal stress is 300 lb./in.², and the unit shear is 100 lb./in.². Find the normal stress and the shear at this point in a plane inclined at 30° to the horizontal.

**Solution.** Suppose a small cube cut out of the beam at the point $N$ (Fig. 10). Then, by the theorem in Article 23, there will also be a unit shear of intensity $q$ on the top and bottom faces of the cube. In the present case, therefore, $p_x = 300$ lb./in.², $p_y = 0$, and $q = 100$ lb./in.². Substituting these values in equations (2) and (3), and putting $\alpha = 30°$, the unit normal stress and unit shear on a plane through $N$ inclined at 30° to the horizontal are $p' = 161.5$ lb./in.², $q' = 179.8$ lb./in.².

**26. Maximum normal stress.** The condition that $p'$ shall be a maximum or a minimum is that  

$$\frac{dp'}{d\alpha} = 0.$$  

Applying this condition to equation (2),

(4)  

$$0 = -\frac{p_y - p_x}{2} 2 \sin 2\alpha + 2q \cos 2\alpha;$$  

whence

(5)  

$$\tan 2\alpha = \frac{2q}{p_y - p_x},$$  

and consequently

(6)  

$$\alpha = \frac{1}{2} \tan^{-1} \left( \frac{2q}{p_y - p_x} + \frac{\lambda \pi}{2} \right),$$
where \( \lambda \) is zero or an arbitrary integer, either positive or negative. Equation (6) gives the angles which the planes containing the maximum and minimum normal stresses make with the horizontal.

From equation (5),

\[
\sin 2\alpha = \pm \frac{2q}{\sqrt{4q^2 + (p_x - p_y)^2}}, \quad \cos 2\alpha = \pm \frac{p_y - p_x}{\sqrt{4q^2 + (p_x - p_y)^2}}.
\]

Substituting these values of \( \sin 2\alpha \) and \( \cos 2\alpha \) in equation (2), the maximum and minimum values of the normal stress are found to be

\[
p_{\text{max}} = \frac{p_x + p_y}{2} \pm \frac{1}{2} \sqrt{4q^2 + (p_x - p_y)^2}.
\]

27. Principal stresses. Since \( \lambda \) in equation (6) is an integer, the two values of \( \alpha \) given by this equation differ by 90°, and, consequently, the planes containing the maximum and minimum normal stresses are at right angles. The maximum and minimum normal stresses are called principal stresses, and the directions in which they act, principal directions.

From equation (3), the right member of equation (4) is equal to \( 2q' \). But since equation (4) is the condition for a maximum or minimum value of the normal stress, it is evident that the normal stress is greatest or least when the shear is zero.

The results of this article can therefore be summed up in the following theorem.

Through each point of a body subjected to planar strain there are two principal directions at right angles, in each of which the shear is zero.

Problem 24. Find the principal stresses and the principal directions at a point in a vertical cross section of a beam at which the unit normal stress is 400 lb./in.\(^2\) and the unit shear is 250 lb./in.\(^2\).

Solution. In this problem \( p_x = 400 \) lb./in.\(^2\), \( p_y = 0 \), and \( q = 250 \) lb./in.\(^2\). Therefore, from equation (6),

\[
\alpha = \frac{1}{2} \tan^{-1} \frac{5}{4} + \frac{\lambda \pi}{2} = -25° 40.2', \text{ or } +64° 19.8';
\]

and from equation (7),

\[
p_{\text{max}} = 520 \text{ lb./in.}^2, \quad p_{\text{min}} = -120 \text{ lb./in.}^2.
\]
28. Maximum shear. The condition that $q'$ shall be a maximum or a minimum is that $\frac{dq'}{d\alpha} = 0$. Applying this condition to equation (3),

$$0 = \frac{p_x - p_y}{2} \cos 2\alpha - 2q \sin 2\alpha;$$

whence

$$\tan 2\alpha = \frac{p_x - p_y}{2q}.$$  \hspace{1cm} (8)

By comparing equations (5) and (8) it is evident that $\tan 2\alpha$, from (8), equals $-\cot 2\alpha$, from (5). Therefore the values of $2\alpha$ obtained from these equations differ by $90^\circ$, and hence the values of $\alpha$ differ by $45^\circ$. Therefore the planes of maximum and minimum shear are inclined at $45^\circ$ to the planes of maximum and minimum normal stress.

From equation (8),

$$\sin 2\alpha = \pm \frac{p_x - p_y}{\sqrt{4q^2 + (p_x - p_y)^2}}, \quad \cos 2\alpha = \pm \frac{2q}{\sqrt{4q^2 + (p_x - p_y)^2}}.$$

Substituting these values of $\sin 2\alpha$ and $\cos 2\alpha$ in equation (3), the maximum and minimum values of the shear are found to be

$$q'_{\max_{\min}} = \pm \frac{1}{2} \sqrt{4q^2 + (p_x - p_y)^2}. \hspace{1cm} (9)$$

It is to be noticed that the maximum and minimum values of the shear given by equation (9) are equal in absolute amount and differ only in sign, which agrees with the theorem stated in Article 23.

Problem 25. Find the maximum and minimum values of the shear in Problem 24, and their directions.

29. Linear strain. If a body is strained in only one direction, the strain is said to be linear. For instance, a vertical post supporting a weight, or a rod under tension, is subjected to linear strain. The unit normal stress and unit shear acting on any inclined section of a body strained in this way can be obtained by supposing the axes of coordinates drawn in the principal directions and putting $q = 0$ and $p_y = 0$ in equations (2) and (3). These values can also be derived independently, as follows.
Consider an elementary triangular prism, and let the axis of $X$ be drawn in the direction of the linear strain. The stresses acting on the prism will then be as shown in Fig. 11. Let $dF$ denote the area of the inclined face. Then the area of the vertical face is $dF \sin \alpha$. Resolving $p_x$ into components parallel to $p'$ and $q'$ respectively, the conditions of equilibrium are

$$p_x \sin \alpha (dF \sin \alpha) = p'dF, \quad p_x \cos \alpha (dF \sin \alpha) = q'dF$$

or, dividing by $dF$,

$$p' = p_x \sin^2 \alpha, \quad q' = \frac{p_x}{2} \sin 2\alpha.$$

From the condition $\frac{d\theta'}{d\alpha} = 0$, it is found that the maximum shear occurs when $\alpha = 45^\circ$, and its value is

$$q'_{\text{max}} = \frac{p_x}{2}.$$

For $\alpha = 0^\circ$ or $90^\circ$, $q' = 0$. Consequently, there is no shear in planes parallel or perpendicular to the direction of the linear strain.

Problem 26. A wrought-iron bar 4 in. wide and $\frac{1}{2}$ in. thick is subjected to a pull of 10 tons. What is the unit shear and unit normal stress on a plane inclined at $30^\circ$ to the axis of the strain? Also what is the maximum unit shear in the bar?

30. Stress ellipse. Suppose that an elementary triangular prism is cut out of a body subjected to planar strain, so that two sides of the prism coincide with the principal directions. Then, by Article 27, the shears in these two sides are zero. Now let the axes of coordinates be drawn in the principal directions, and resolve the stress acting on the inclined face of the prism into
components parallel to the axes instead of into normal and shearing stresses as heretofore. Then, from Fig. 12, if \(dF\) denotes the area of the inclined face, the conditions of equilibrium are

\[
\begin{align*}
 p'_x dF &= p_x dF \sin \alpha, \\
 p'_y dF &= p_y dF \cos \alpha;
\end{align*}
\]

whence

\[
\frac{p'_x}{p_x} = \sin \alpha, \quad \frac{p'_y}{p_y} = \cos \alpha.
\]

Squaring and adding,

\[
\frac{p'^2_x}{p^2_x} + \frac{p'^2_y}{p^2_y} = 1,
\]

which is the equation of an ellipse with semi-axes \(p_x\) and \(p_y\), the coordinates of any point on the ellipse being \(p'_x\) and \(p'_y\). Consequently, if the stress acting on the inclined face of the prism is calculated for all values of \(\alpha\), and these stresses are represented in magnitude and direction by lines radiating from a common center, the locus of the ends of these lines will be an ellipse called the stress ellipse (Fig. 13).

31. Simple shear. If a body is compressed in one direction and equally elongated in a direction at right angles to the first, the strain is planar. In this case, if the axes are drawn in the principal directions, \(q = 0\), \(p_x = -p_y\), and the stress ellipse becomes the circle \(p'^2_x + p'^2_y = p^2_x\).

Moreover, the normal stress in the planes of maximum or minimum shear is zero; for by substituting in equation (2) the values of \(\sin 2\alpha\) and \(\cos 2\alpha\) obtained from equation (8), the normal stress in the planes of maximum or minimum shear is found to be \(\frac{p_x + p_y}{2}\), and this is zero since \(p_x = -p_y\).

Substituting \(q = 0\) and \(p_x = -p_y\) in equation (9), Article 28, the maximum or minimum value of the shear in the present case is

\[
q'_{\text{max}} = \pm p_x;
\]

\[
q'_{\text{min}} = \pm p_x;
\]
that is to say, the intensity of the shear in the planes of zero normal stress is equal to the maximum value of the normal stress.

To give a geometrical representation of the conditions of the problem, suppose a small cube cut out of the body with its faces inclined at 45° to the principal directions. Then the only stresses acting on the inclined faces of this cube are shears equal in amount to the principal stresses. The strain in this case is called \textbf{simple shear}.

Conversely, if a small cube is subjected to simple shear, as indicated in Fig. 15, tensile stresses equal in amount to this shear occur in the diagonal plane \(AC\) of the cube, and compressive stresses of like amount in the diagonal plane \(BD\).

\textbf{Problem 27.} The steel propeller shaft of a steamship is subjected to a shearing stress of 10,000 lb./in.\(^2\). Find the maximum tensile stress in the shaft.

\textbf{32. Coefficient of expansion.} Consider an infinitesimal prism of dimensions \(dx\), \(dy\), \(dz\), and suppose that under strain these dimensions become \(dx + s_x dx\), \(dy + s_y dy\), \(dz + s_z dz\), where \(s_x\), \(s_y\), \(s_z\) are the unit deformations in the directions of the edges of the prism. Then the volume of the prism becomes

\[ V + dV = (dx + s_x dx)(dy + s_y dy)(dz + s_z dz), \]

or, neglecting infinitesimals of an order higher than the first,

\[ V + dV = (1 + s_x + s_y + s_z)dx dy dz. \]

Let \(K = s_x + s_y + s_z\). Then the change in the volume of the prism due to the strain is

\[ dV = Kdx dy dz. \]
RELATIONS BETWEEN STRESS AND DEFORMATION

For this reason \( K \) is called the **coefficient of cubical expansion** (or contraction) of the body.

From this definition it is evident that for temperature stresses the coefficient of cubical expansion is three times the coefficient of linear expansion.

From Article 9, for linear tensile strain,

\[
s_x = -\frac{s_z}{m}.
\]

Consequently, in this case,

\[
K = s_x - \frac{s_x - s_z}{m} = \frac{m - 2}{m} s_x = \frac{m - 2}{m} \frac{P_x}{E}.
\]

Since the prism is certainly not decreased in volume by a tensile strain, \( K \) cannot be negative and therefore \( m - 2 \geq 0 \), or \( m \geq 2 \). If \( m = 2 \), \( K = 0 \), which means that the body is incompressible. Therefore 2 is the lower limit of Poisson's constant.

33. **Modulus of elasticity of shear.** In an elementary prism subjected to simple shear an angular deformation occurs, as shown in Fig. 16. Let the angle of deformation \( \phi \) be expressed in circular measure. Then, for materials which conform to Hooke's law,

\[
\frac{q}{\phi} = G,
\]

where \( G \) is a constant called the **modulus of elasticity of shear**, or **modulus of rigidity**. Since the angle \( \phi \), expressed in circular measure, is an abstract number, \( G \) must have the dimensions of \( q \), and can therefore be expressed in lb./in.\(^2\), as in the case of Young's modulus.

Tabulated values of the modulus of elasticity of shear and ultimate shearing strength for various substances are given in Article 22.

**Problem 28.** A \( \frac{1}{4} \)-in. wrought-iron bolt has a diameter of .62 in. at base of thread, with a nut \( \frac{1}{4} \) in. thick. What force acting on the nut will strip the thread off the bolt?
Problem 29. What force will pull the head off the bolt in Problem 28, if the head is of the same thickness as the nut?

Problem 30. A 1⁄4-in. rivet connects two plates which transmit a tension of 2500 lb. Assuming that the shear is uniformly distributed over the cross section of the rivet, find the unit shear on the rivet.

Problem 31. An eyebar is designed to carry a load of 15 tons. What must be the size of the pin to be safe against shear?

NOTE. Consider the pin in double shear, and assume that this shear is uniformly distributed over the cross section of the pin.

34. Relation between the elastic constants. Suppose a cube is subjected to compressive stress on one pair of opposite faces and tensile stress on another pair of opposite faces. Then, if the axes of $X$ and $Y$ are drawn in the direction of the strain, $P_x = -P_Y$; and the strain is one of simple shear, as explained in Article 31.

Let $x$ denote the length of an edge of the cube before strain. Under the strain the cube becomes a parallelepiped, its increase in length in the direction of the $X$-axis, due to the tensile stress $P_x$, being $\frac{xP_x}{E}$; and its increase in length in this direction, due to the compressive stress $-P_x$, being $\frac{XP_x}{mE}$.

Therefore, if $dx$ denotes the total increase in length in the direction of the $X$-axis,

$$dx = \frac{xP_x}{E} + \frac{xP_x}{mE},$$

or, since $P_x = q$,

$$dx = \frac{m+1}{mE} xq.$$

By reason of the strain the angle between the diagonals is increased by an amount $\phi$, and therefore the angle between a diagonal and a side is increased by $\frac{\phi}{2}$. From the right triangle $ABC$ (Fig. 17),
\[ \tan \left( \frac{\pi}{4} + \frac{\phi}{2} \right) = \frac{x + dx}{x - dx}. \]

From trigonometry,

\[ \tan \left( \frac{\pi}{4} + \frac{\phi}{2} \right) = \frac{1 + \tan \frac{\phi}{2}}{1 - \tan \frac{\phi}{2}}. \]

Since \( \phi \) is assumed to be very small, \( \tan \frac{\phi}{2} = \frac{\phi}{2} \), approximately, and therefore

\[ \frac{1 + \frac{\phi}{2}}{1 - \frac{\phi}{2}} = \frac{x + dx}{x - dx}; \]

whence

\[ \phi = \frac{2 dx}{x} = \frac{2(m + 1)}{mE} q. \]

By definition, \( G = \frac{q}{\phi} \). Therefore

\[ G = \frac{m}{2(m + 1)} E, \]

which expresses the relation between the elastic constants \( G, E \), and \( m \).

**Problem 32.** From the values of \( G \) and \( E \), given in Article 22, determine the value of \( m \) for cast iron.

**35. Measure of strain.** In general, the unit deformation \( s \) is taken as the measure of a strain. The calculation of \( s \), however, involves a knowledge of the modulus of elasticity \( E \), and for many materials the latter is difficult to determine. To obviate this difficulty, any given strain may be compared with a linear strain which is produced by a unit stress equal to the maximum allowable unit stress. The stress which would produce this linear strain is called the **equivalent stress.**

To illustrate the application of this method, consider a planar strain in which \( p_1 \) and \( p_2 \) denote the principal stresses and \( s_1, s_2 \) the corresponding unit deformations. Then, by Hooke's law,
Let \( p_e \) denote the equivalent unit stress. Then, from the above definition of \( p_e \), it must be so chosen as to produce either \( s_1 \) or \( s_2 \), whichever is the greater. Consequently

\[
(13) \quad p_e = Eh \quad \text{or} \quad p_e = Es.
\]

Comparing equations (12) and (13),

\[
(14) \quad p_e = p_1 - \frac{1}{m} p_2 \quad \text{or} \quad p_e = p_2 - \frac{1}{m} p_1.
\]

The value of the equivalent stress can thus be calculated directly from the two principal stresses. In order that the strain be safe, the greater of the two values of \( p_e \) found from equation (14) must not exceed the maximum allowable unit stress.

**Problem 33.** Find the value of the equivalent stress in Problem 24, and compare it with the principal stresses.

**36. Combined bending and torsion.** One of the most important applications of the preceding paragraph is to the calculation of the equivalent stress in a beam subjected simultaneously to bending and torsion.

Let the axis of \( X \) be drawn in the direction of the axis of the beam. Then on any cross section of the beam there will be a normal stress \( p_x \) due to bending, and a shearing stress \( q \) due to torsion, while the stress between adjacent longitudinal fibers is zero, that is, \( p_y = 0 \). Therefore, from equation (7), the principal stresses are

\[
p_1 = \frac{1}{2} (p_x + \sqrt{4q^2 + p_x^2}) \quad \text{and} \quad p_2 = \frac{1}{2} (p_x - \sqrt{4q^2 + p_x^2}).
\]

Consequently, from equation (14), the equivalent stress is

\[
(15) \quad p_e = \frac{m - 1}{2m} p_x + \frac{m + 1}{2m} \sqrt{4q^2 + p_x^2}.
\]

**Problem 34.** A round steel shaft used for transmitting power bears a transverse load. At the most dangerous section the normal stress due to bending is 5000 lb./in.\(^2\) and the shear due to torsion is 8000 lb./in.\(^2\). Calculate the intensity of the equivalent stress.
CHAPTER III

ANALYSIS OF STRESS IN BEAMS

37. System of equivalent forces. The theory of beams deals, in general, with the stresses produced in a prismatic body by a set of external forces in static equilibrium. Ordinarily these forces all lie in one plane; in this case it is proved in mechanics that they can be replaced by a single force acting at any given point in this plane, and a moment. To balance this equivalent system of external forces, the stresses acting on any cross section of the beam must also consist of a single force and a moment, the point of application of this single force being conveniently chosen as the center of gravity of the cross section.

The following special cases are of frequent occurrence.

If the moment is zero and the single force through the center of gravity of a cross section acts in the direction of the axis of the beam, the strain is simple tension or compression; if it is perpendicular to the axis of the beam, the strain is simple shear.

If the single force is zero and the plane of the moment passes through the axis of the beam, pure bending strain occurs; if the single force is zero and the plane of the moment is perpendicular to the axis of the beam, a twisting strain called torsion is produced. These two cases are illustrated in Fig. 18, A and B.

If the plane of the moment forms an arbitrary angle with the axis of the beam, the moment can be resolved into two components whose planes are parallel and perpendicular respectively to the axis of the beam. In this case the strain consists of combined bending and torsion.

If the single force through the center of gravity is inclined to the axis of the beam, it can be resolved into two components,—one in the
direction of the axis, called the *axial loading*, and the other perpendicular to the axis, called the *shear*.

38. **Common theory of flexure.** In the majority of practical cases of flexure (or bending) of beams, the external forces acting on the beam all lie in one plane through its axis and are perpendicular to this axis. The single force through the center of gravity of any cross section is then perpendicular to the axis of the beam, and the plane of the moment passes through this axis. The theory based on the assumption of this condition of strain is called the **common theory of flexure**.

39. **Bernoulli's assumption.** In order to obtain a starting point for the analysis of stress in beams, the arbitrary assumption is made that *a cross section of the beam which was plane before flexure remains plane after flexure*. This assumption was first made by Bernoulli, and since his time has formed the basis for all investigations in the theory of beams.*

40. **Curvature due to bending moment.**

The effect of the external moment on a beam originally straight is to cause its axis to become bent into a curve, called the *elastic curve*. Since, by Bernoulli's assumption, any cross section of the beam remains identical with itself during deformation, any two consecutive cross sections of the beam which were perpendicular to its axis before flexure will remain perpendicular to it after flexure, and will therefore intersect in a center of curvature of the elastic curve, as shown in Fig. 19.

The fibers of the beam between these two cross sections were originally of the same length. After flexure, however, it will be found that the fibers on the convex side have been lengthened by a certain amount \(AB\), while those on the concave side have been shortened by an amount \(CD\).† Between these two there must lie a strip of fibers

*St. Venant has shown that Bernoulli's assumption is rigorously true only for certain forms of cross section. For materials which conform to Hooke's law, however, it is sufficiently exact to assure results approximately correct.

† This can be shown experimentally by placing two thin steel strips in longitudinal grooves in a wooden beam, one on the upper side and the other on the lower side, so that
which are neither lengthened nor shortened. The horizontal line in which this strip intersects any cross section is called the neutral axis of the section.

41. Consequence of Bernoulli’s assumption. From Fig. 19, it is evident that as a consequence of Bernoulli’s assumption the lengthening or shortening of any longitudinal fiber is proportional to its distance from the neutral axis. But, by Hooke’s law, the stress is proportional to the deformation produced. Therefore the stress on any longitudinal fiber is likewise proportional to its distance from the neutral axis. Navier was the first to deduce this result from Bernoulli’s assumption.

If, then, the stresses are plotted for every point of a vertical strip MN (Fig. 20), their ends will all lie in a straight line, and consequently this distribution of stress is called the straight-line law.

42. Result of straight-line law. In rectangular coördinates let the axis of Z coincide with the neutral axis, and the axis of Y be perpendicular to it and in the plane of the cross section. Then if the normal stress at the distance y from the neutral axis is denoted by \( p \), and that at a distance \( y_0 \) is denoted by \( p_0 \), from the straight-line law,

\[
\frac{p}{p_0} = \frac{y}{y_0}
\]

Since in order to equilibrate the external bending moment the normal stresses must also form a moment, the sum of the compressive stresses must equal the sum of the tensile stresses. Therefore, since the tensile and compressive stresses are of opposite sign, the algebraic sum of all the normal stresses acting on the section must be zero, that is to say, \( \int p dF = 0 \), where \( dF \) is the infinitesimal area on which \( p \) acts.

Inserting the value of \( p \) from (16),

the strips are free to slide longitudinally but are otherwise fixed. If the strips are of the same length as the beam before bending, it will be found that after bending the upper strip projects beyond the ends of the beam, while the lower strip does not reach the ends. Experiments of this kind have been made by Morin and Tresca. See Unwin, The Testing of Materials of Construction, p. 36.
\[ \int p dF = \frac{P_0}{y_0} \int y dF = 0, \]

and therefore
\[ \int y dF = 0. \]

But the distance of the center of gravity of the section from the axis of \( Z \) (or neutral axis) is given by
\[
\bar{y} = \frac{\int y dF}{\int dF}.
\]

Therefore, since \( \int y dF = 0 \), \( \bar{y} \) must be zero, and consequently the neutral axis passes through the center of gravity of the section.

**43. Moment of inertia.** For equilibrium, the moment of the normal stresses acting on any cross section must equal the moment of the external forces at this section. Therefore, if \( M \) denotes the moment of the external forces, or **external bending moment**, as it is called,
\[ \int p y dF = M, \]

or, from (16),
\[ \frac{P_0}{y_0} \int y^2 dF = M. \]

The integral \( \int y^2 dF \) depends only on the form of the cross section, and is called the **moment of inertia** of the cross section with respect to the neutral axis.

Let the moment of inertia be denoted by \( I \). Then
\[ I = \int y^2 dF, \]

and, consequently,
\[ P_0 = \frac{My_0}{I}. \]

This formula gives the intensity of the normal stress \( p_0 \) at the distance \( y_0 \) from the neutral axis, due to an external bending moment \( M \). If
\( p \) denotes the stress on the extreme fiber and \( e \) denotes the distance of this fiber from the neutral axis, then, from (17),

\[
(18) \quad p = \frac{Me}{I}.
\]

Equation (18) gives the maximum normal stress on any cross section of a beam, and is the fundamental formula in the common theory of flexure.

**Problem 35.** Find the moment of inertia of a rectangle of height \( h \) and breadth \( b \) about a gravity axis \( * \) parallel to its base.

\[
\text{Solution.} \quad I_x = \int_{-\frac{h}{2}}^{\frac{h}{2}} (bdy) y^2 = \frac{bh^3}{3} = \frac{bh^3}{12}.
\]

**Problem 36.** Find the moment of inertia of a triangle of base \( b \) and altitude \( h \) about a gravity axis parallel to its base.

**Problem 37.** Find the moment of inertia of a circle of diameter \( d \) about a gravity axis.

**Problem 38.** The external moment acting on a rectangular section 12 in. deep and 4 in. wide is 30,000 ft. lb. Find the stress on the extreme fiber.

\[
\text{Solution.} \quad M = 30,000 \text{ ft. lb.} = 300,000 \text{ in. lb.,}
\]
\[
I_x = \frac{bh^3}{12} = 576 \text{ in.}^4.
\]
\[
\therefore \quad p = \frac{Me}{I} = 3750 \text{ lb./in.}^2.
\]

**44. Moment of resistance.** The moment of resistance is defined as the moment of the internal stresses which balances the external moment \( M \). According to this definition the moment of resistance is simply

\[
\frac{pl}{e},
\]

since \( \frac{pl}{e} = M \). Therefore, if \( p \) is the maximum allowable unit stress for any material, the moment of resistance \( \frac{pl}{e} \) determines the maximum external bending moment which can be safely carried by a beam of this material.

*In what follows, "gravity axis" will be used as an abbreviation for "axis through the center of gravity."*
For instance, consider an oak beam 8 in. deep and 4 in. wide. From Article 22, the ultimate compressive strength for timber may be taken as 7000 lb./in.², and the ultimate tensile strength as 10,000 lb./in.². Therefore, using a factor of safety of 8, the safe unit stress is \( p = 875 \text{ lb./in.}² \). For the beam under consideration \( I = 170.7 \text{ in.}^4 \) and \( e = 4 \text{ in.} \). Consequently, the maximum bending moment which the beam can be expected to carry safely is 37,340 in. lb., or 3112 ft. lb.

**Problem 39.** Find the moment of resistance of a circular cast-iron beam 6 in. in diameter.

**Problem 40.** Find the moment of resistance of a Carnegie steel I-beam, No. B 1, weighing 80 lb./ft.

**Problem 41.** Compare the moments of resistance of a rectangular beam 8 in. \( \times \) 14 in. in cross section, when placed on edge and when placed on its side.

**45. Section modulus.** In Article 43 the moment of inertia was defined as the integral

\[ I = \int y^2 \, dF. \]

From this definition, it is apparent that the moment of inertia depends for its value solely on the form of the cross section. Since it is independent of all other considerations, it may therefore be called the shape factor in the strength of materials.

Since \( e \) denotes the distance of the extreme fiber of a beam from the neutral axis, the ratio \( \frac{I}{e} \) is also a function of the shape of the cross section, and for this reason is called the section modulus. Let the section modulus be denoted by \( S \). Then \( S = \frac{I}{e} \), and the expression for the moment of resistance becomes

\[ M = pS. \]

This expresses the fact that the strength of a beam depends jointly on the form of cross section and the ultimate strength of the material.

**Problem 42.** Find the section moduli for the sections given in Problems 35, 36, and 37 respectively.

**Problem 43.** Compare the section moduli for a rectangle 10 in. high and 4 in. wide, and for one 4 in. high and 10 in. wide.

**46. Theorems on the moment of inertia.** The following is a summary of the most useful theorems concerning the moment of inertia. The proofs can be found in any standard text-book on mechanics.

(A) Let \( I_g \) denote the moment of inertia of any cross section with respect to a gravity axis (see footnote, p. 37), \( I_n \) the moment of inertia
of the same section with respect to any parallel axis, \( c \) the distance between the two axes, and \( F \) the area of the cross section. Then

\[
I_n = I_y + Fe^2.
\]

(E) Every section has two axes through its center of gravity, called principal axes, such that for one of these the moment of inertia is a maximum, and for the other is a minimum. Let the principal axes be taken for the axes of \( Y \) and \( Z \) respectively. Then if \( I_y \) and \( I_z \) denote the moments of inertia of the section with respect to these axes, and \( I_a \) denotes the moment of inertia with respect to an axis inclined at an angle \( \alpha \) to the axis of \( Z \),

\[
I_a = I_z \cos^2\alpha + I_y \sin^2\alpha.
\]

(C) The moment of inertia of a compound section about any axis is equal to the sum of the moments of inertia about this axis of the various parts of which the compound section is composed.

(D) The moment of inertia of any section with respect to an axis through its center of gravity and perpendicular to its plane is called the polar moment of inertia. The polar moment of inertia is defined by the equation

\[
I_p = \int r^2 dF,
\]

where \( r \) is the distance of the infinitesimal area \( dF \) from the center of gravity of the section.

Since \( r^2 = y^2 + z^2 \),

\[
\int r^2 dF = \int y^2 dF + \int z^2 dF,
\]

whence

\[
I_p = I_y + I_z.
\]

(E) Let \( I_1 \) and \( I_2 \) denote the moments of inertia of any section with respect to its principal axes. Then \( I_p = I_1 + I_2 \), and, consequently,
(22) \[ I_y + I_z = I_1 + I_2; \]

that is to say, the sum of the moments of inertia with respect to any two rectangular axes in the plane of the section is constant.

\((F)\) The numerical value of the moment of inertia is expressed as the fourth power of a unit of length. Therefore the quantity \( \frac{I}{F} \) is the square of a length called the radius of gyration, and will be denoted by \( t \). The radius of gyration is thus defined by the equation

\[ (23) \quad t = \sqrt{\frac{I}{F}}, \]

and is the average value of the distances of all the infinitesimal elements of area from the axis with respect to which \( I \) is taken.

The meaning to be attached to the radius of gyration is that if the total area of the figure was concentrated in a single point at a distance \( t \) from the axis, the moment of inertia of this single particle about this axis would be equal to the given moment of inertia.

**Problem 44.** Find the moment of inertia of the rectangle in Problem 35 about its base, and also the corresponding radius of gyration.

*Solution.* \[ I_z = \frac{bh^3}{12} + (bh) \left( \frac{h}{2} \right)^2 = \frac{bh^3}{3}, \quad t_z = \frac{h}{\sqrt{3}}. \]

**Problem 45.** Find the moment of inertia of the above rectangle about a gravity axis inclined at an angle of \( 30^\circ \) to its base.

**Problem 46.** Find the moment of inertia of a rectangular strip, such as that shown in Fig. 24, about a gravity axis parallel to its base.

**Problem 47.** Prove that the moment of inertia of a T-shape, such as that shown in Fig. 25, about a gravity axis parallel to the base is given by the expression

\[ I_z = \frac{bh^3 + bh'^3 - (b - b')d^3}{3}. \]

**Problem 48.** Find the polar moment of inertia and radius of gyration of a circle of diameter \( d \) about an axis through its center.
47. Graphical method of finding the moment of inertia. If the boundary of a given cross section is not composed of simple curves such as straight lines and circles, it is often difficult to find the moment of inertia by means of the calculus. When such difficulties arise the following graphical method may be used to advantage.

To explain the method consider a particular case, such as the rail shape shown in Fig. 26, and suppose that it is required to find the center of gravity of the section, and also its moment of inertia about a gravity axis perpendicular to the web. The first step is to draw two lines, $AB$ and $CD$, parallel to the required gravity axis, at any convenient distance apart, say $l$.

If the section is symmetrical about any axis, such as $OF$ in the figure, it is sufficient to consider the portion on either side of this axis, say the part on the right of $OY$ in the present case.

Now suppose that the cross section is divided into narrow strips parallel to $AB$ and $CD$; let $z$ denote the length of one of these strips, and $dy$ its width. Then, if for each value of $z$ a length $z'$ is found, such that

$$z' = z \frac{y}{l},$$

any point $P$ on the boundary of the original section, with coordinates $z$ and $y$, will be transformed into a point $P'$ with coordinates $z'$ and $y$.

Suppose this process is carried out for a sufficient number of points, and that the points $P'$ so obtained are joined by a curve, as shown by the dotted line in Fig. 26. Let $F$ denote the area of the original curve and $F'$ the area of the transformed curve, both of which can
easily be measured by means of a planimeter. Also let \( N \) denote the \textbf{static moment} of the original section with respect to the line \( AB \), where the static moment — an area with respect to any axis — is defined by the integral

\[
N = \int y \, dF,
\]

in which \( y \) is the distance of an infinitesimal area \( dF \) from the given axis. The static moment is thus equal to the area of the section multiplied by the distance of its center of gravity from the given axis. Then

\[
N = \int y \, dF = \int yz \, dy = l \int z' \, dy = lF'.
\]

But, from the above definition,

\[
N = cF,
\]

where \( c \) is the distance of the center of gravity of the original section from the line \( AB \). Therefore \( cF = lF' \); whence

\[
c = l \frac{F'}{F},
\]

which determines the position of the center of gravity.

To find the moment of inertia, make a second transformation by constructing for each \( z' \) a value \( z'' \), such that

\[
z'' = z' \frac{y}{l}.
\]

Then the points \( P' \) on the first transformed curve are transformed into a series of points \( P'' \) on another curve, shown by the broken line in Fig. 26. Let the area of this second curve be denoted by \( F'' \). Then, since \( z'' = z' \frac{y}{l} \) and \( z' = z \frac{y}{l} \), we have \( z'' = z \frac{y^2}{l^2} \). Consequently,

\[
I = \int y^2 \, dF = \int y^2z \, dy = l^2 \int z' \, dy = l^2F'',
\]

which gives the moment of inertia of the original section with respect to the line \( AB \).
ANALYSIS OF STRESS IN BEAMS

43

If the moment of inertia \( I_g \) with respect to a gravity axis is required, then, since by Article 46 (A), \( I = I_g + c^2 F \), we have \( I_g = I - c^2 F \); and hence, by substituting the values of \( I \) and \( c \) from the above,

\[
I_g = I + \frac{c^2 (F'' - c^2)}{F}.
\]

The above method is due to Nehrs, and furnishes an easy method of calculating the moment of inertia of any cross section by simply measuring the area \( F' \) of the original section and the area \( F'', F''' \) of the transformed sections by means of a planimeter, and then substituting these values in the above formulas.

48. Moment of inertia of non-homogeneous sections. The standard formula for calculating the stress in beams, \( \sigma = \frac{Mc}{I} \), assumes that the material of which the beam is composed is homogeneous throughout. If, then, a beam is composed of two different materials, such, for instance, as concrete and steel, it is necessary to modify this formula somewhat before applying it.

To exemplify this, consider a rectangular concrete beam, reënforced by steel rods near the bottom, as shown in cross section in Fig. 27. Let \( p_c \) and \( p_s \) denote the stresses on a fiber of concrete and of steel respectively, at the same distance \( y \) from the neutral axis, and let \( E_c \) and \( E_s \) denote the moduli of elasticity for concrete and steel. Then, by Hooke's law,

\[
\frac{p_s}{E_s} = y = \frac{p_c}{E_c};
\]

whence

\[
p_s = \frac{E_s}{E_c} p_c.
\]

Therefore, if \( dF \) is an infinitesimal area of steel at the distance \( y \) from the neutral axis, the moment of the stress acting on this area is

\[
y p_s dF = y \frac{E_s}{E_c} p_c dF = y p_c \left( \frac{E_s}{E_c} dF \right).
\]
Consequently, the intensity of the fiber stress can be considered to vary directly as its distance from the neutral axis over the entire cross section of the beam, provided the area of the steel is increased in the ratio \( \frac{E_s}{E_c} \). If, then, the depth is kept constant, the breadth must be increased in this ratio, and the cross section thus obtained will appear as shown in Fig. 28. Therefore, if \( I_c \) denotes the moment of inertia of this modified section, the stress in the extreme fiber is given by the formula

\[
P = \frac{Me}{I_c}
\]

**Problem 49.** A rectangular concrete beam 14 in. deep and 8 in. wide is reinforced by two \( \frac{3}{4} \)-in. square steel rods placed 1 in. from the bottom, as shown in Fig. 29. Assuming that the ratio of the moduli of elasticity of steel and concrete is \( E_s: E_c = 15:1 \), find the moment of inertia of a cross section of the beam about a gravity axis parallel to the base.

**Solution.** Increasing the area of the steel in the rate 15:1, it becomes 16.9 in.\(^2\). The area of the concrete included in the same horizontal strip with the steel is
ANALYSIS OF STRESS IN BEAMS

4.9 in.². Consequently, the breadth of the lower flange of the equivalent homogeneous section is

\[ \frac{16.9 + 4.9}{.75} = 29.1 \text{ in.} \]

The distance of the center of gravity of this equivalent section below the top is found to be 7.69 in., and its moment of inertia about the gravity axis OZ is 2269 in.⁴ (Fig. 30).

49. Inertia ellipse. Dividing equation (20) by \( F \) and expressing the result in terms of the radii of gyration by means of equation (23),

\[ (24) \quad t_{\alpha}^2 = t_{y}^2 \cos^2 \alpha + t_{z}^2 \sin^2 \alpha, \]

where \( t_{y} \) and \( t_{z} \) are the radii of gyration with respect to the axes of \( Y \) and \( Z \) respectively, and \( t_{\alpha} \) is the radius of gyration with respect to a gravity axis inclined at an angle \( \alpha \) to the axis of \( Z \).

Now let \( l \) be a length defined by the relation \( \frac{t_{y} t_{z}}{t_{\alpha}} = l \). Then \( t_{y} = \frac{l t_{\alpha}}{t_{y}}, t_{z} = \frac{l t_{\alpha}}{t_{z}}; \) and substituting these values of \( t_{y} \) and \( t_{z} \) in equation (24), it becomes

\[ t_{\alpha}^2 = \frac{t_{y}^2}{l^2} \cos^2 \alpha + \frac{t_{z}^2}{l^2} \sin^2 \alpha, \]

or, dividing by \( t_{\alpha}^2 \),

\[ 1 = \frac{(l \cos \alpha)^2}{t_{y}^2} + \frac{(l \sin \alpha)^2}{t_{z}^2}. \]

This is the equation of an ellipse with semi-axes \( t_{y} \) and \( t_{z} \), called the inertia ellipse, the coordinates of any point of the curve being \( l \cos \alpha \) and \( l \sin \alpha \).

By means of the inertia ellipse the moment of inertia with respect to any gravity axis \( AB \) (Fig. 31) can be obtained as follows.

The equation of a tangent to the ellipse \( \frac{z^2}{a^2} + \frac{y^2}{b^2} = 1 \) at the point \( (z', y') \) is \( \frac{z z'}{a^2} + \frac{y y'}{b^2} = 1 \), or

\[ (25) \quad z z' b^2 + y y' a^2 - a^2 b^2 = 0. \]
It is proved in analytical geometry that in order to reduce the linear equation \( Az + By + C = 0 \) to the normal form \( z \cos \beta + y \sin \beta - c = 0 \), it is necessary to divide throughout by \( \sqrt{A^2 + B^2} \). Applying this theorem to equation (25), it becomes

\[
\frac{z'^2}{\sqrt{z'^2b^4 + y'^2a^4}} z + \frac{y'^2}{\sqrt{z'^2b^4 + y'^2a^4}} y - \frac{a^2b^2}{\sqrt{z'^2b^4 + y'^2a^4}} = 0,
\]

where

\[
\frac{z'^2}{\sqrt{z'^2b^4 + y'^2a^4}} = \cos \beta, \quad \frac{y'^2}{\sqrt{z'^2b^4 + y'^2a^4}} = \sin \beta, \quad \frac{a^2b^2}{\sqrt{z'^2b^4 + y'^2a^4}} = c.
\]

Substituting these values in the expression \( a^2 \cos^2 \beta + b^2 \sin^2 \beta \), it becomes

\[
a^2 \cos^2 \beta + b^2 \sin^2 \beta = \frac{a^2b^4z'^2}{z'^2b^4 + y'^2a^4} + \frac{b^2a^4y'^2}{z'^2b^4 + y'^2a^4} = \frac{a^2b^2(z'^4a^2 + a^2y'^2)}{z'^2b^4 + y'^2a^4} = \frac{a^4b^4}{z'^2b^4 + y'^2a^4} = c^2;
\]

whence, since \( \beta = \alpha \pm \frac{\pi}{2} \),

\[
c^2 = a^2 \cos^2 \beta + b^2 \sin^2 \beta = a^2 \sin^2 \alpha + b^2 \cos^2 \alpha.
\]

Since the semi-axes of the inertia ellipse are \( a = t_y \) and \( b = t_z \), this expression becomes

\[
c^2 = t_y^2 \sin^2 \alpha + t_z^2 \cos^2 \alpha,
\]
or, comparing this expression with equation (24),

\[
c = t_z.
\]

The radius of gyration corresponding to any gravity axis \( AB \) can therefore be found by drawing a tangent to the inertia ellipse parallel to \( AB \), and measuring the distance of this tangent from the center.

Since the inertia ellipse is constructed on the principal radii of gyration as semi-axes, it can be drawn on all the ordinary forms of cross section, and when this is done the method given above greatly simplifies the calculation of the moment of inertia with respect to any gravity axis which is not a principal axis.

**Problem 50.** From the Carnegie handbook of structural steel the principal radii of gyration of T-shape, No. 72, size 3 in. by 4 in., are 1.23 in. and .50 in. Construct the inertia ellipse (Fig. 32).
Problem 51. For a Carnegie I-beam, No. B 7, 15 in. deep and weighing 42 lb./ft., the principal radii of gyration are 5.95 in. for an axis perpendicular to web at center, and 1.08 in. for an axis coincident with web at center. Construct the inertia ellipse.

Problem 52. For a Cambria channel, No. C 21, depth of web 7 in., width of flanges 2.51 in., thickness of web .63 in., the radius of gyration about an axis perpendicular to the web at center is 2.39 in.; the distance of the center of gravity from outside of web is .58 in., and the radius of gyration about an axis through the center of gravity parallel with center line of web is .56 in. Construct the inertia ellipse.

Problem 53. In Problems 47, 48, and 49 determine graphically the radii of gyration about an axis through the center of gravity and inclined at 30° to the major axis of the inertia ellipse.

50. Vertical reactions and shear. Under the assumptions of the common theory of flexure, the external forces acting on a beam all lie in the same vertical plane. Therefore, since the beam is assumed to be in equilibrium, the sum of the reactions of the supports must equal the total load on the beam.

For instance, consider a simple beam AB of length \( l \), which is supported at the ends and bears a single concentrated load \( P \) at a distance \( d \) from \( A \) (Fig. 33). Let \( R_1 \) and \( R_2 \) denote the reactions at \( A \) and \( B \) respectively. Then, from the above,

\[
R_1 + R_2 = P.
\]

To find the values of \( R_1 \) and \( R_2 \), take moments about either end, say \( A \). Then

\[
R_2 l = Pd;
\]

whence

\[
R_2 = \frac{Pd}{l}.
\]

Also, since

\[
R_1 + R_2 = P,
\]

\[
R_1 = \frac{P(l - d)}{l}.
\]

If any cross section of a beam is taken, the stresses acting on this section must reduce to a single force and a moment, as explained in
Article 37. For a simple beam placed horizontally and supporting a system of vertical loads, the plane of the moment is perpendicular to the plane of the section, and the single force is a vertical shear lying in the plane of the section. Therefore, since the portion of the beam on either side of the section must be in equilibrium, the vertical shear is equal to the algebraic sum of the external forces on either side of the section. Thus, if the portion of the beam on the left of the section is considered, the vertical shear on the section is equal to the reaction of the left support minus the sum of the loads on the left of the section.

Problem 54. A beam 10 ft. long bears a uniform load of 300 lb./ft. Find the vertical shear on a section 4 ft. from the left support.

Solution. The total load on the beam is 3000 lb. Therefore, since the load is uniform, each reaction is equal to 1500 lb. The load on the left of the section is 300 \times 4 = 1200 lb. Therefore the vertical shear on the section is 1500 - 1200 = 300 lb.

Problem 55. Find the vertical shear at the center and ends of the beam in the preceding problem.

Problem 56. A beam 12 ft. long bears loads of 1, \( \frac{1}{2} \), and 3 tons at distances of 2, 5, and 7 ft. respectively from the left support. Find the vertical shear at either end of the beam, and also at a point between each pair of loads.

51. Maximum bending moment. The external bending moment at any point of a beam is defined as the sum of the moments, about the neutral axis of a cross section through the point, of all the external forces on either side of the section. Thus, if the portion of the beam on the left of the section is considered, the external moment at this point is the moment of the reaction of the left support about the neutral axis of the section, minus the sum of the moments of the loads between the left support and the section, about the same neutral axis.

For example, in Fig. 34 the moment of \( R_1 \) about the neutral axis of the section \( mn \) is \( R_1x \), and the moment of \( P_1 \) about the same axis is \( P_1(x - d_1) \). Therefore the total external moment acting on the section \( mn \) is

\[
M = R_1x - P_1(x - d_1).
\]
As another example, consider a beam of length $l$ bearing a uniform load of amount $w$ per unit of length. Then the total load on the beam is $wl$, and each reaction is $\frac{wl}{2}$. Therefore the moment at a point distant $x$ from the left support is

$$M = \frac{wl}{2} \cdot x - wx \cdot \frac{x}{2} = \frac{wx}{2}(l - x).$$

From this relation it is evident that $M$ is zero for $x = 0$ or $l$, and attains its maximum value for $x = \frac{l}{2}$; that is to say, the bending moment is zero at either end of the beam and a maximum at the center.

From the formula $M = pS$, given in Article 45, it is evident that the maximum value of the stress $p$ occurs where the bending moment $M$ is a maximum. Ordinarily the maximum bending moment produces a greater strain than the maximum shear; therefore the section at which the maximum moment occurs is called the **dangerous section**, since it is the section at which the material is most severely strained, and consequently the one at which rupture may be expected to occur.

In order to find the maximum bending stress in a beam, the formula $M = pS$ is written

$$p = \frac{M}{S}.$$

The maximum bending stress is then obtained at once by simply dividing the maximum bending moment by the section modulus.

**Problem 57.** A rectangular wooden beam 14 ft. long, 4 in. wide, and 9 in. deep bears a uniform load of 75 lb./ft. Find the position and amount of the maximum bending moment.

**Problem 58.** Find the maximum bending stress in the beam in the preceding problem.

**Problem 59.** A Cambria I-beam, No. B 33, which weighs 40 lb./ft., is 15 ft. long and bears a single concentrated load of 5 tons at its center. Find the maximum bending stress in the beam, taking into account the weight of the beam.

52. **Bending moment and shear diagrams.** In general, the bending moment and shear vary from point to point along a beam. This variation is shown graphically in the following diagrams for several different systems of loading.

(A) **Simple beam bearing a single concentrated load $P$ at its center** (Fig. 35). From symmetry the reactions $R_1$ and $R_2$ are each equal to $\frac{P}{2}$. Let $mn$ be any section of the beam at a distance $x$ from the left support, and consider the portion of the beam on the left of this
section. Then the moment at mn is $R_1x\left(=\frac{P}{2}x\right)$ and the shear is $R_1\left(=\frac{P}{2}\right)$. For a section on the right of the center the bending moment is $R_2(l - x)$ and the shear is $R_2$. Consequently, the bending moment varies as the ordinates of a triangle, being zero at either support, and attaining a maximum value of $\frac{Pl}{4}$ at the center, while the shear is constant from A to B, and also constant, but of opposite sign, from B to C.

The diagrams in Fig. 35 represent these variations in bending moment and shear along the beam under the assumed loading. Consequently, if the ordinates vertically beneath B are laid off to scale to represent the bending moment and shear at this point, the bending moment and shear at any other point D of the beam are found at once from the diagram by drawing the ordinates EF and HK vertically beneath D.

(B) Beam bearing a single concentrated load P at a distance c from one support.

The reactions in this case are

$$R_1 = \frac{P(l - c)}{l}$$

and

$$R_2 = \frac{Pc}{l}.$$  

Hence the bending moment
at a distance $x$ from the left support is

$$R_x x = \frac{P(l - c)x}{l}$$

provided $x < c$, and

$$R_x(l - x) = \frac{Pc(l - x)}{l}$$

if $x > c$. If $x = c$, each of these moments becomes

$$\frac{Pc(l - c)}{l},$$

and consequently the bending moment and shear diagrams are as shown in Fig. 36.

(C) Beam bearing several separate loads.

In this case the bending moment diagram is obtained by constructing the diagrams for each load separately and then adding their ordinates, as indicated in Fig. 37.

(D) Beam bearing a continuous uniform load.

Let the load per unit of length be denoted by $w$. Then the total load on the beam is $wl$, and the reactions are

$$R_1 = R_2 = \frac{wl}{2}.$$ 

Hence at a distance $x$ from the left support the bending moment $M_x$ is
The bending moment diagram is therefore a parabola. For \( x = \frac{l}{2} \),
\[ M_x = \frac{w l^2}{8} \],
which is its maximum value. The bending moment and shear diagrams are therefore as represented in Fig. 38.

(E) Beam bearing uniform load over part of the span.

Let the load extend over a distance \( c \) and be of amount \( w \) per unit of length. Then the total load is \( wc \). The reactions of the supports are the same as though the load was concentrated at its center of gravity \( G \). Therefore, if \( d \) denotes the distance of \( G \) from the left support,

\[ R_2 = \frac{wcd}{l} \quad \text{and} \quad R_1 = \frac{wc(l-d)}{l}. \]

Also, the bending moment diagrams for the portions \( AB \) and \( CD \) are the same as though the load was concentrated at \( G \), and are therefore the straight lines \( A'H \) and \( D'K \), intersecting in the point \( T \) vertically beneath \( G \) (Fig. 39).

From \( B \) to \( C \) there is an additional bending moment due to the uniform load on this portion of the beam. Thus, if \( LMN \) is the parabolic moment diagram for a beam of length \( LN \) or \( c \), the ordinates to the line \( HK \) must be increased by those to the parabola \( LMN \), giving as a complete moment diagram the line \( A'HJKD' \).
Analytically, if \( x \) denotes the distance of any section from the left support, the equations of the three portions \( AH, HJK, \) and \( KD' \) of the moment diagram are

\[
M_{AB} = R_1x = \frac{w(c(l-d)x)}{l}, \quad \text{for} \quad 0 \leq x \leq d - \frac{c}{2};
\]

\[
M_{BC} = R_1x - \frac{w(x-d+\frac{c}{2})^2}{2} = \frac{w(c(l-d)x)}{l} - \frac{w(x-d+\frac{c}{2})^2}{2},
\]

\[
M_{CD} = R_2x = \frac{w(c(l-x))}{l}, \quad \text{for} \quad d + \frac{c}{2} \leq x \leq l.
\]

**Problem 60.** Construct the bending moment and shear diagrams for a cantilever bearing a single concentrated load \( P \) at the end.

**Problem 61.** Construct the bending moment and shear diagrams for a simple beam bearing two equal concentrated loads at equal distances from the center.

53. Relation between shear and bending moment.
Consider a beam bearing several concentrated loads \( P_1, P_2, \) etc., at distances \( d_1, d_2, \) etc., from the left support. Take any section \( mn \) at a distance \( x \) from the left support, and consider the portion of the beam on the left of this section. Then if \( Q \) denotes the total shear on this section,

\[
Q = R_1 - \sum_{0}^{x} P.
\]

Also, the bending moment at \( mn \) is

\[
M = R_1x - \sum_{0}^{x} P(x - d),
\]

where the summations include all the loads between \( A \) and the section \( mn.\)

* A cantilever is a beam which is framed into a wall or other support at one end and projects outward from this support.*
Differentiating $M$ with respect to $x$,

$$\frac{dM}{dx} = R_1 - \sum \frac{x}{P}.$$

Therefore

(26) \hspace{1cm} \frac{dM}{dx} = Q; \hspace{1cm}

that is to say, the shear at any point of a beam is the first differential coefficient of the bending moment at that point.

If the beam is uniformly loaded, as in (D) of the preceding article, $Q = R_1 - wx$ and $M = R_1 x - \frac{wx^2}{2}$, from which equation (26) results as before.

From equation (26) it follows that if the bending moment is constant the shear is zero; and conversely, if the shear is zero the bending moment is constant. But $\frac{dM}{dx} = 0$ is the condition that the bending moment shall be either a maximum or a minimum. Consequently, at a point where the bending moment passes through a maximum or minimum value the shear is zero; and conversely. This theorem is illustrated by the bending moment and shear diagrams in the preceding paragraph.

54. Designing of beams In designing beams the problem is to find the transverse dimensions of a beam of given length and given material, so that it shall bear a given load with safety.

In order to solve this problem, the formula $M = pS$ is written

$$\frac{M}{p} = S.$$

Then, from the given loading, the maximum value of $M$ is determined, and by dividing the ultimate strength of the material by the proper factor of safety the safe unit stress $p$ becomes known. The quotient of these two gives the section modulus of the required section.

In the handbooks issued by the various structural iron and steel companies, the section moduli of all the standard sections are tabulated. If, then, the beam is to be of a standard shape, its size is found by simply looking in the tables for the value of $S$ which corresponds most closely to the calculated value $\frac{M}{p}$, the value chosen.
being equal to or greater than the calculated value in order to insure safety.

If the section of the beam is to be of a shape not listed in the handbooks, the dimensions of the section must be found by trial. Thus a section of the required shape is assumed, and its section modulus calculated from the relation

\[ S = \frac{I}{e} \]

If the value of \( S \) thus found is too great or too small, the dimensions of the section are decreased or increased, and \( S \) again calculated. Proceeding in this way, the dimensions of the section are changed until a value of \( S \) is found which is approximately equal to the calculated value \( \frac{M}{P} \).

**Problem 62.** Design a steel I-beam, 10 ft. long, to bear a uniform load of 1600 lb./ft., neglecting its own weight.

**Problem 63.** A built beam is to be composed of two steel channels placed on edge and connected by latticing. What must be the size of the channels if the beam is to be 18 ft. long and bear a load of 10 tons at its center, the factor of safety being given as 4?

**Problem 64.** Compare the strength of a pile of 10 boards, each 14 ft. long, 1 ft. wide, and 1 in. thick, when the boards are piled horizontally, and when they are placed close together on edge.

**Problem 65.** Design a rectangular wooden cantilever to project 4 ft. from a wall and bear a load of 500 lb. at its end, the factor of safety being 8.

**Problem 66.** A rectangular cantilever projects a distance \( l \) from a brick wall and bears a single concentrated load \( P \) at its end. How far must the inner end of the cantilever be imbedded in the wall in order that the pressure between this end and the wall shall not exceed the crushing strength of the brick?

**Solution.** Let \( b \) denote the width of the beam and \( x \) the distance it extends into the wall. For equilibrium the reaction between the beam and the wall must consist of a vertical force and a moment. If \( p_a \) denotes the intensity of the vertical
stress, and it is assumed to be uniformly distributed over the area \( bx \), \( p_a bx = P \); whence \( p_a = \frac{P}{bx} \) (see Fig. 41, a).

Similarly, let \( p_b \) denote the maximum intensity of the stress forming the stress couple. Then, taking moments about the center \( C \) of the portion \( AB \), since the stress forming the couple is also distributed over the area \( bx \), we have

\[
I = \frac{bx^2}{12}, \quad e = \frac{z}{2}, \quad \text{and} \quad M = P \left( l + \frac{x}{2} \right).
\]

Therefore, substituting in the formula \( p = \frac{Me}{I} \), we have

\[
p_b = \frac{P \left( l + \frac{x}{2} \right)}{\frac{3bx^2}{12}} = \frac{6P \left( l + \frac{x}{2} \right)}{bx^2}.
\]

Consequently,

\[
p_{\text{max}} = p_b \pm p_a = \frac{6P \left( l + \frac{x}{2} \right)}{bx^2} \pm \frac{P}{bx};
\]

whence

\[
p_{\text{max}} = 2P \frac{b}{bx} \left( 2 + \frac{3l}{x} \right),
\]

and

\[
p_{\text{min}} = 2P \frac{b}{bx} \left( 1 + \frac{3l}{x} \right) \ast
\]

As a numerical example of the above, let \( l = 5 \text{ ft.} = 60 \text{ in.}, P = 200 \text{ lb.}, b = 4 \text{ in.}, \) and \( p = 600 \text{ lb./in.}^2 \) (for ordinary brick work). Solving the above equation by the formula for quadratics,

\[
x = \frac{2P \pm \sqrt{4P^2 + 6bpP_1}}{bp};
\]

whence, by substituting the above values,

\[
x = 5.6 \text{ in.}
\]

†55. Distribution of shear over rectangular cross section. Consider a cross section of a rectangular beam at a distance \( x \) from the left support, as \( MNRS \) in Fig. 42, and let \( P \) be a point in this cross section at a distance \( y \) from the neutral axis. Then, by equation (17), Article 43, the unit normal stress at \( P \) is \( p = \frac{My}{I} \). If the cross

† For a brief course in the Strength of Materials the remainder of this chapter may be omitted.
section is moved from this position parallel to itself a distance $dx$, say to the position $EFGH$ in the figure, the intensity of the stress at $P$ is increased by the amount

$$\frac{dp}{dx} = \frac{dM}{dx} \cdot \frac{y}{I} = \frac{y}{I} Q.$$ \hspace{1cm} (27)

The difference between the normal stresses acting on these two adjacent cross sections tends to shove the point $P$ in a direction parallel to the axis of the beam, and this tendency is resisted by a shearing stress of intensity $q$ at $P$, also parallel to the axis of the beam. Therefore, since the resultant normal stress on the area $BCEF$ is $\int_c^h dp \cdot dF$, and the resultant shearing stress on the area $ABCD$ is $qbdx$,

$$\int_c^h dp \cdot dF = qbdx.$$

Substituting the value of $dp$ from equation (27),

$$\frac{Qdx}{I} \int_c^h ydF = qbdx;$$

whence

$$q = \frac{Q}{bI} \int_c^h ydF. \hspace{1cm} (28)$$

Formula (28) applies to any cross section bounded by parallel sides.

In Article 23 it was proved that whenever a shearing stress acts along any plane in an elastic solid, there is always another shearing stress of equal intensity acting at the same point in a plane at right angles to the first. Consequently, formula (28) also gives the intensity of the stress at any point $P$ in a direction perpendicular to the neutral axis of the section.

For a rectangular cross section

$$\int_c^h ydF = \int_c^h bydy = b\left(\frac{h^2}{8} - \frac{c^2}{2}\right),$$

and hence

$$q = \frac{Q}{bI}\left(\frac{h^2}{8} - \frac{c^2}{2}\right). \hspace{1cm} (29)$$
From equation (29), it is evident that for rectangular sections the shear is zero at the top and bottom of the beam \((c = \frac{h}{2})\) and increases toward the center as the ordinates to a parabola. For \(c = 0\), \(q\) attains its maximum value, namely, \(q = \frac{Qh^2}{8I}\). This distribution of shear over the cross section is represented in Fig. 43. At the top and bottom where the normal bending stress is greatest the shear is zero, and at the center where the normal stress is zero the shear is a maximum.

By finding the area of the parabola \(ABC\) it is easily proved that the maximum intensity of the shearing stress is \(\frac{3}{8}\) of its average value.

56. Distribution of shear over circular cross section. For a rectangular cross section the shear parallel to the neutral axis is zero, but for a circular cross section this is not the case. Let Fig. 44 represent a circular cross section, say the cross section of a rivet subjected to a vertical shear, and let it be required to find the direction and intensity of the shear at the extremity \(N\) of a horizontal line \(MN\). If the stress at \(N\) has a normal component, that is, a component in the direction \(ON\), it must have a component of equal amount through \(N\) perpendicular to the plane of the cross section, that is, in the direction of the axis of the rivet (Article 23). Consequently, since the rivet receives no stress in the direction of its axis, the stress at \(N\) can have no normal component and is therefore tangential.

Similarly, the stress at \(M\) is tangential, and since the line \(MN\) is horizontal the tangents at \(M\) and \(N\) must meet at some point \(B\) on the vertical diameter, which is taken for the \(Y\)-axis. The stress at any point \(K\) on the \(Y\)-axis must act in the direction of this axis, and
therefore also pass through $B$. For any other point of $MN$ it is approximately correct to assume that the direction of the stress also passes through $B$.

Therefore, in order to determine the direction and intensity of the shear at any point of a circular cross section, a chord is drawn through the point perpendicular to the direction of the shear and tangents drawn at its extremities, thus determining a point such as $B$ in Fig. 44. Assuming the axes as in Fig. 44, the vertical shear acting at the point is then calculated by formula (28), where, in the present case, $b$ is the length of the chord and the integral is extended over the segment above the chord. The horizontal component of the shear is then determined by the condition that the resultant of these two components must pass through $B$.

The amount of the component and resultant shears acting at any point can be calculated as follows.

For a strip parallel to the $Z$-axis, $dF = zdy$, and $z = \sqrt{r^2 - y^2}$. Therefore

$$\int_{h}^{r} ydF = 2 \int_{h}^{r} \sqrt{r^2 - y^2} ydy = -\frac{2}{3} (r^3 - y^3) \left|_{h}^{r} \right. = \frac{b^3}{12}.$$  

The vertical component of the shear is, therefore,

$$q_{v} = \frac{Q}{bl} \left( \frac{b^3}{12} \right) = \frac{Qb^2}{3 \pi r^4}.$$  

Let $KB$ and $KN$, Fig. 44, represent in magnitude and direction the vertical and horizontal components of the shear acting at $N$. Then, from the similar triangles $KNB$ and $KNO$,

$$\frac{KN}{KB} = \frac{KO}{KN}, \text{ or } \frac{q_{x}}{q_{v}} = \frac{h}{b} = \frac{b}{2};$$  

whence

$$q_{x} = \frac{2q_{x}b}{b} = \frac{2Qbh}{3 \pi r^4}.$$  

Since $BN^2 = BK^2 + KN^2$, the resultant shear at $N$ is

$$q = \sqrt{q_{v}^2 + q_{x}^2} = \frac{Qb}{3 \pi r^4} \sqrt{b^2 + 4h^2},$$
or, since \( \frac{b^2}{4} + h^2 = r^2 \),

\[
q = \frac{2Qb}{3\pi r^3}.
\]

In this equation \( q \) is proportional to \( b \), and hence the maximum value of \( q \) is at the center where \( b = 2r \). Hence

\[
q_{\text{max}} = \frac{4Q}{3\pi r^3}.
\]

The maximum unit shear on a circular cross section is therefore equal to \( \frac{4}{3} \) of its average value.

57. Cases in which shear is of especial importance. In Article 53 it was shown that at points where the normal bending stress is a maximum the shear is zero. For this reason it is usually sufficient to dimension a beam so as to carry the maximum bending stress safely without regard to the shear. However, in certain cases, of which the following are examples, it is necessary to calculate the shear also, and combine it with the bending stress.

For an I-beam the static moment \( \int ydF \) is nearly as great directly under the flange as for a section through the neutral axis; and therefore, by formula (28), the shear is very large at this point, as shown on the shear diagram in Fig. 45. Hence the shear and bending stress are both large under the flange, and the resultant stress at this point may, in some cases, exceed that at the outer fiber.

Again, if a beam is very short in comparison with its depth, or if the material of which it is made offers small resistance to shear in certain directions, as in the case of a wooden beam parallel to the grain, a special investigation of the shear must be made. For instance, consider a rectangular wooden beam of length \( l \), breadth \( b \), and depth \( h \), bearing a single concentrated load \( P \) at its center. Then the total
shear on any section is \( \frac{P}{2} \), and the maximum bending moment is \( \frac{Pl}{4} \).

Hence the maximum unit normal stress is

\[
p = \frac{M}{I} \frac{h}{2} = \frac{3PL}{2bh^2}.
\]

Also, since \( Q = \frac{P}{2} \) and \( \int ydF = \frac{bh^2}{8} \), the maximum unit shear is

\[
q = \frac{Q}{bI} \int ydF = \frac{3P}{4bh}.
\]

Now let \( \kappa \) denote the ratio between the tensile strength in the direction of the fiber and the shearing strength parallel to the fiber. Then, in order that the beam shall be equally safe against normal and shearing stress, \( p = \kappa q \), or

\[
\frac{3PL}{2bh^2} = \kappa \frac{3P}{4bh};
\]

whence

\[
\frac{2L}{h} = \kappa.
\]

In general, \( \kappa \) is not greater than 10. If \( \kappa = 10 \), \( L = 5h \). Consequently, if the length of a beam is greater than 5 times its depth, the shear is not likely to cause rupture.

**Problem 67.** The bending moment and shear at a certain point in a Carnegie I-beam, No. B 2, of the dimensions given in Fig. 46, are \( M = 200,000 \text{ ft. lb.} \) and \( Q = 15,000 \text{ lb.} \) respectively. Calculate the maximum normal stress and the equivalent stress for a point directly under the flange, and compare these values with the normal stress in the extreme fiber.

**Solution.** From the Carnegie handbook, the moment of inertia of this section about a neutral axis perpendicular to the web is \( I = 1466.5 \text{ in.}^4 \). Consequently, the normal stress in the extreme fiber is

\[
\sigma_{\text{max}} = \frac{Me}{I} = \frac{2,400,000(10)}{1466.5} = 16,365 \text{ lb./in.}^2,
\]

and the normal stress at a point \( P \) under the flange is

\[
p = \frac{2,400,000(0.35)}{1466.5} = 15,300 \text{ lb./in.}^2.
\]
Neglecting the rounded corners,
\[ \int_{k}^{h} ydF = \int_{2.35}^{10} 7ydy = 44 \text{ in.}^2. \]

Consequently, from formula (28), the unit shear at \( P \) is
\[ q = \frac{Q}{bI} \int_{k}^{h} ydF = \frac{15000 (44)}{7(1466.5)} = 64 \text{ lb./in.}^2. \]

At the point \( P \), therefore, \( p_x = 15,300 \text{ lb./in.}^2 \), \( p_y = 0 \), and \( q = 64 \text{ lb./in.}^2 \).

Hence, from formula (7), Article 26,
\[ p_{max} = \frac{p_x}{2} + \frac{1}{2} \sqrt{q^2 + p_y^2} = 15,304 \text{ lb./in.}^2. \]

To calculate the equivalent stress it is necessary to find the principal stresses, which are, from the above,
\[ p_1 = 15,304 \text{ lb./in.}^2 \quad \text{and} \quad p_2 = -2 \text{ lb./in.}^2. \]

Hence, from formula (14), Article 35, for \( m = 3 \frac{1}{2} \) the equivalent stress at \( P \) is
\[ p_e = 15,305 \text{ lb./in.}^2. \]

58. Oblique loading. If, for any cross section, the plane of the external bending moment does not pass through a principal axis of the section, the loading is said to be oblique. In this case the bending moment \( M \) can be resolved into components parallel to the principal axes, namely, \( M \cos \alpha \) and \( M \sin \alpha \), where \( \alpha \) is the angle which the plane containing \( M \) makes with one of the principal axes.

For materials which conform to Hooke's law it has been found that the stress due to several sets of external forces can be calculated for each set separately and then combined into a single resultant. This is called the law of superposition. Applying this law to the present case,
\[ p = \frac{M \cos \alpha}{I_x} \cdot e_z + \frac{M \sin \alpha}{I_y} \cdot e_y = \frac{M \cos \alpha}{S_z} + \frac{M \sin \alpha}{S_y}, \]

where \( e_y, e_z \) are the distances of the extreme fibers of the beam from the axes of \( Y \) and \( Z \) respectively, and \( S_y, S_z \) are the corresponding section moduli.
Problem 68. In an inclined railway the angle of inclination with the horizontal is $30^\circ$. The stringers are 10 ft. 6 in. apart, inside measurement, and the rails are placed 1 ft. inside the stringers. The ties are 8 in. deep and 6 in. wide, and the maximum load transmitted by each rail to one tie is 10 tons. Calculate the maximum normal stress in the tie.

Solution. The bending moment is the same for all points of the tie between the rails, and is 20,000 ft. lb. From Problem 42, $S_x = 64 \text{ in.}^3$ and $S_y = 48 \text{ in.}^3$. Therefore, from equation (30),

$$
P_{\text{max}} = \frac{240,000 \left(\frac{\sqrt{3}}{2}\right)}{64} + \frac{240,000 \left(\frac{1}{2}\right)}{48} = 5744 \text{ lb./in.}^2.
$$

59. Eccentric loading. If the external forces acting on any cross section reduce to a single force $P$, perpendicular to the plane of the section, but not passing through its center of gravity, this force is called an eccentric load. Let $B$ denote the point of application of the eccentric load $P$, and let $x'y'$ denote the coordinates of $B$. Then the eccentric force $P$ acting at $B$ can be replaced by an equal and parallel force acting at the center of gravity $C$ of the section, and a moment whose plane is perpendicular to the section. This moment can then be resolved into two components parallel to the principal axes, of amounts $Py'$ and $Pz'$ respectively. Therefore, by the law of superposition, the intensity of the stress at any point $(y, z)$ of the cross section is

$$
p = \frac{P}{F} + \frac{Pz'}{I_y} z + \frac{Py'}{I_z} y;
$$

or, since $I = F\ell^2$,

$$
p = \frac{P}{F} \left(1 + \frac{zz'}{I_y} + \frac{yy'}{I_z}\right).
$$

At the neutral axis the stress is zero, and consequently $1 + \frac{zz'}{I_y} + \frac{yy'}{I_z}$ must be zero; or, since the semi-axes of the inertia ellipse are $a = t_y$ and $b = t_z$, this condition becomes

$$
\frac{zz'}{a^2} + \frac{yy'}{b^2} = -1.
$$

This condition must be satisfied by every point on the neutral axis, and is therefore the equation of the neutral axis. To each pair of values of $y'$ and $z'$, that is, to each position of the point of application $B$ of the eccentric load, there corresponds one and only one position of the neutral axis.
If the point $B$ lies on the ellipse \[ \frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \]
its coordinates must satisfy this equation, and, consequently,

\[ \frac{z'^2}{a^2} + \frac{y'^2}{b^2} = 1. \]  

In this case the neutral axis passes through a point on the ellipse diametrically opposite to $B$; for if $-z', -y'$ are substituted for $y$ and $z$ in equation (31), it is evident that the condition (32) is satisfied.

The tangent to the ellipse \[ \frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \] at the point $-z', -y'$ is \[ \frac{zz'}{a^2} + \frac{yy'}{b^2} = -1, \]
which is identical with equation (31). Consequently, if $B$ lies on the inertia ellipse, the neutral axis corresponding to $B$ is tangent to the ellipse at the point diametrically opposite to $B$.

From equation (31), the slope of the tangent is found to be \[ \frac{b^2z'}{a^2y'}. \]

If, then, the point $B$ moves out along a radius $CB$, $z'$ and $y'$ increase in the same ratio, and consequently the slope is constant; that is to say, if $B$ moves out along a radius, the neutral axis moves parallel to itself.

As $z'$ and $y'$ increase, $z$ and $y$ must decrease, for the products $zz'$ and $yy'$ must be constant in order to satisfy equation (31). Therefore the farther $B$ is from the center of gravity, the nearer the corresponding neutral axis is to the center of gravity, and vice versa.

If, in Fig. 48, $TN$ is the neutral axis corresponding to $B$, it follows, from the above, that $CB \cdot CT$ is a constant wherever $B$ is on the line $BT$. But if $B$ lies on the ellipse, the corresponding neutral axis is tangent to the ellipse at the point diametrically opposite to $B$, and in this case the above product becomes $CM^2$. Therefore

\[ CB \cdot CT = CM^2. \]

From this relation, the position of the neutral axis can be determined when the position of the point $B$ is given.
60. **Antipole and antipolar.** The theorems in the preceding paragraph prove that if the point of application of an eccentric load lies outside, on, or within the inertia ellipse, the corresponding neutral axis cuts this ellipse, is tangent to it, or lies wholly outside it. This relation is analogous to that of poles and polars in analytical geometry, except that in the present case the point and its corresponding line lie on opposite sides of the center instead of on the same side. For this reason the point in the present case is called the **antipole**, and its corresponding line the **antipolar**.

The following theorem is analogous to a well-known theorem of poles and polars.

If the antipole moves along a fixed straight line, the antipolar revolves about a fixed point. Conversely, if the antipolar revolves about a fixed point, the antipole moves along a fixed straight line.

If the antipole moves to infinity, the antipolar, or neutral axis, passes through the center of gravity of the section, which is the ordinary case of pure bending strain. The bending moment in this case can be considered as due to an infinitesimal force at an infinite distance from the center of gravity.

If the antipole coincides with the center of gravity, the neutral axis lies at infinity, which means that the stress is uniformly distributed over the cross section.

Since the stresses on opposite sides of the neutral axis are of opposite sign, if the neutral axis cuts the cross section, stresses of both signs occur (i.e. both tension and compression), whereas if the neutral axis lies outside the cross section, the stress on the section is all of the same sign (i.e. either all tension or all compression).

61. **Core section.** Let it be required to find all positions of the point of application of an eccentric load such that the stress on the cross section shall all be of the same sign. From the preceding article, the condition for this is that the neutral axis shall not cut the cross section. If, then, all possible lines are drawn touching the cross section or having one point in common with it, and the antipoles of these lines are found, the locus of these antipoles will form a closed figure, called the **core section**.

For a point within or on the boundary of the core section the neutral axis lies entirely without the cross section, or, at most, touches it,
and consequently stress of only one sign occurs. For a point without the core section the corresponding neutral axis cuts the cross section and it is subjected to stresses of both signs.

**Problem 69.** Construct the core section for a rectangular cross section of breadth \( b \) and height \( h \) (Fig. 49).

**Solution.** From Problem 35, \( I_x = \frac{bh^3}{12} \), \( I_y = \frac{hb^3}{12} \), and the corresponding radii of gyration are \( t_x = \frac{I_x}{F} = \frac{h^2}{12} \) and \( t_y = \frac{b^2}{12} \). Consequently, the semi-axes of the inertia ellipse are \( t_x = \frac{h}{2 \sqrt{3}} \) and \( t_y = \frac{b}{2 \sqrt{3}} \). Having constructed the inertia ellipse, the vertices of the core section will be antipoles of the lines \( PQ, QR, RS, \) and \( SP \).

From Article 59, the antipole of \( PQ \) is determined by the relation \( OA \cdot OE = OH^2 \), or, since \( OE = \frac{h}{2} \) and \( OH = t_x = \frac{h}{2 \sqrt{3}} \), \( OA = \frac{h}{6} \). Similarly, \( OC = \frac{h}{6} \) and \( OB = OD = \frac{b}{6} \).

Thus the core section is the rhombus \( ABCD \), of which the vertices \( A, B, C, D \) are the antipoles of the lines \( PQ, PS, SR, QR \) respectively, and the sides \( AB, BC, CD, DA \) are the antipolars of the points \( P, S, R, Q \) respectively.

**Problem 70.** Construct the core section for the T-shape in Problem 50.

**Solution.** Six lines can be drawn which will have two or more points in common with the perimeter of the T-shape without crossing it, namely, \( PQ, QR, RT, TU, US, \) and \( SP \) (Fig. 50). The vertices \( A, B, C, D, E \) of the core section are then the antipoles of these six lines respectively.

**Problem 71.** Construct the core section of the I-beam in Problem 51.

**Problem 72.** Construct the core section for the channel in Problem 52.

**Problem 73.** Construct the inertia ellipse and core section for a circular cross section.

62. **Application to concrete and masonry construction.** Since concrete and masonry are designed to carry only compressive stresses, it
is essential that the point of application of the load shall lie within the core section.

Consider a rectangular cross section of breadth \( b \) and height \( h \). For the gravity axes \( MM \) and \( NN \) (Fig. 51) the corresponding moments of inertia are

\[
I_m = \frac{hb^3}{12} \quad \text{and} \quad I_n = \frac{bh^3}{12}.
\]

Hence the radii of gyration are

\[
t_m = \frac{b}{\sqrt{12}} = .2887 b \quad \text{and} \quad t_n = \frac{h}{\sqrt{12}} = .2887 h,
\]

and the inertia ellipse is constructed on these as semi-axes. To determine the core section it is sufficient to find the antipole of each side of the cross section \( PQRS \). Suppose \( A \) is the antipole of \( PQ \), \( B \) the antipole of \( PS \), etc. Then, by Article 60, the antipole of any line through \( P \), such as \( LL \), lies somewhere on \( AB \); that is to say, as the line \( PQ \) revolves around \( P \) to the position \( PS \), its antipole moves along \( AB \) from \( A \) to \( B \). The core section in the present case is thus found to be the rhombus \( ABCD \).

From Article 59, \( OC \cdot OK = OT^2 = \frac{h^2}{12} \), since the semi-axes of the ellipse are the radii of gyration. But \( OK = \frac{h}{2} \); hence \( OC = \frac{h}{6} \) and \( AC = \frac{h}{3} \). Similarly, \( BD = \frac{b}{3} \). This proves the correctness of the rule ordinarily followed in masonry construction, namely, that in order to insure that the stress shall all be of the same sign, the center of pressure must fall within the middle third of the cross section.

63. Calculation of pure bending strain by means of the core section. Let Fig. 52 represent the cross section of a beam subjected to pure bending strain. In this case the neutral axis passes through the center of gravity of a cross section, and therefore, from Article 60, the strain can be considered as due to an infinitesimal force at an infinite distance from the origin. Under this assumption the stress
due to pure bending strain can be readily calculated by means of the core section, as follows.

Suppose the external bending moment $M$ lies in a plane perpendicular to the plane of the cross section and intersecting it in the line $MM$. Then, assuming that $M$ is due to an infinitesimal force whose point of application is at an infinite distance from $O$ in the direction $OM$, the antipolar of this point will be the diameter of the inertia ellipse conjugate to $MM$. It is proved in analytical geometry that the tangent at the end of a diameter of a conic is parallel to the conjugate diameter. Therefore, if $BT$ is tangent to the inertia ellipse at $B$, and $NN$ is drawn through $O$ parallel to $BT$, $NN$ will be the diameter conjugate to $MM$. Since the greatest stress occurs on the fiber most distant from the neutral axis, the maximum stress will occur at $P$ or $R$. Through $P$ draw $PA$ parallel to $NN$ and intersecting $MM$ in $A$. Then, from Article 59,

$$OA \cdot OK = OB^2,$$

or, taking the projections of $OA$, $OK$, and $OB$ on a line perpendicular to $NN$,

$$e \cdot OK \sin \alpha = (OB \sin \alpha)^2,$$

where $e$ is the perpendicular distance of $PA$ from $O$. But $OB \sin \alpha$ is the distance of the tangent $BT$ from $O$, and, by Article 49, this distance is the radius of gyration $t$ corresponding to the axis $NN$. Therefore

$$e \cdot OK \sin \alpha = t^2 = \frac{I_n}{F};$$

where $F$ is the area of the section and $I_n$ is its moment of inertia with respect to $NN$. The component of the external moment $M$ perpendicular to $NN$ is $M \sin \alpha$. Hence, equating this to the internal moment,

$$M \sin \alpha = \frac{p_0}{e} \int y(ydF) = \frac{p_0}{e} \int y^2dF = \frac{p_0 I_n}{e},$$

where $p_0$ is the stress at the distance $e$ from the neutral axis. Substituting in equation (34) the value of $I_n$ obtained from equation (35),
whence

\( p_0 = \frac{M}{F' \cdot OK} \)  

If, in the handbooks issued by iron and steel companies, the inertia ellipse and core section were drawn on each cross section tabulated, the calculation of the maximum bending stress by formula (36) would be extremely simple, requiring merely the measurement of the distance OK.

Problem 74. Calculate the maximum bending stress in Problem 68 by means of the core section.

Solution. The loading is as represented in Fig. 53, in which the portion BC is subjected to pure bending strain. From Problem 68, \( M = 20,000 \) ft. lb. and \( F = 48 \) in.². From the diagram of the core section drawn to scale, OK is found to measure .9 in. Therefore, from formula (36), \( p_0 = 5555 \) lb./in.².

64. Stress trajectories. In Article 27 the principal stresses at any point in a body were defined as the maximum and minimum normal stresses at this point. Lines which everywhere have the direction of the principal stresses are called stress trajectories.

In order to determine the stress trajectories, a number of cross sections of the body are taken, and the shear and normal stress calculated for a number of points in each section. The directions which the principal stresses at these points make with the axis of the body can then be found by formula (6), Article 26, as explained in Problem 24. The stress trajectories are thus determined as the envelopes of these tangents.

Since the principal stresses at any point are always at right angles, the stress trajectories constitute a family of orthogonal curves.

65. Materials which do not conform to Hooke's law. The preceding articles of this chapter are based on Hooke's law, and consequently the results are applicable only to materials which conform to this law, such as steel, wrought iron, and wood. Other materials, such as cast iron, stone, brick, cement, and concrete, are so lacking in homogeneity that their physical properties are very uncertain, differing not
only for different specimens of the material but also for different portions of the same specimen. For this reason it is impossible to apply to such materials a general method of analysis with any assurance that the results will approximate the actual behavior of the material. For practical purposes, however, the best method is to calculate the strength of such materials by the formulas deduced above, and then modify the result by a factor of safety so large as to include all probable exceptions.

The behavior of cast iron is more uncertain than that of any other material of construction, and for this reason its use is to be avoided if possible. If two pieces from the same specimen are subjected to tensile strain and to cross-bending strain respectively, it will be found that the ultimate strength deduced from the cross-bending test is about twice as great as that deduced from the tensile test. The reason for this is that the neutral axis does not pass through the center of gravity of a cross section, lying nearer the compression than the tension side, and also because the stresses increase more slowly than their distances from the neutral axis. If, then, it becomes necessary to design a cast-iron beam, the ultimate tensile strength used in the calculation should be that deduced from tensile tests.

For materials such as concrete, stone, and cement, the most rational method of procedure is to introduce a correction coefficient \( \eta \) in formula (18) and put

\[
P = \eta \frac{Me}{l},
\]

where it has been found by experiment that for granite \( \eta = .96 \), for sandstone \( \eta = .84 \), and for concrete \( \eta = .97 \).*

CHAPTER IV
FLEXURE OF BEAMS

66. Elastic curve. If a beam is subjected to transverse loading, its axis is bent into a curve called the elastic curve. The differential equation of the elastic curve is found as follows.

Let $ABDE$ (Fig. 54) represent a portion of a bent beam limited by two adjacent cross sections $AB$ and $DE$, and let $C$ be a point in the intersection of these two cross sections. Then $C$ is the center of curvature of the elastic curve $FH$. Let $d\beta$ denote the angle $ACE$, and through $H$ draw $LK$ parallel to $AC$; then the angle $LHE$ is also equal to $d\beta$. Since the normal stress is zero at the neutral axis, the fiber $FH$ is unchanged in length by the strain. Therefore, from Fig. 54, the change in length of a fiber at a distance $y$ from the elastic curve is $yd\beta$, where $d\beta$ is expressed in circular measure. Consequently, the deformation of such a fiber is

$$s = \frac{yd\beta}{x}.$$  

By Hooke’s law, $p = E$ where $p = \frac{My}{I}$; hence

$$\frac{My}{Is} = E.$$  

71
Inserting in this expression the value of \( s \) just found, \( \frac{Myx}{Iyd\beta} = E \); whence

\[
d\beta = \frac{Mx}{EI}.
\]

Let the radius of curvature \( CF \) of the elastic curve be denoted by \( \rho \). Then \( \rho d\beta = x \), and inserting this value of \( d\beta \) in the above equation, it becomes

\[
\rho = \frac{EI}{M}.
\]

From the differential calculus, the radius of curvature of any curve can be expressed by the formula

\[
\rho = \left[ 1 + \left( \frac{dy}{dx} \right)^2 \right]^{\frac{1}{2}} \frac{d^2y}{dx^2}.
\]

But since the deformation of the beam is assumed to be small, the slope of the tangent at any point of the elastic curve is small; that is to say, \( \frac{dy}{dx} \) is infinitesimal, and consequently \( \left( \frac{dy}{dx} \right)^2 \) can be neglected in comparison with \( \frac{d^2y}{dx^2} \). Under this assumption \( \rho = \frac{1}{\frac{d^2y}{dx^2}} \), and therefore \( \frac{EI}{M} = \rho = \frac{1}{\frac{d^2y}{dx^2}} ; \) whence

\[
EI \frac{d^2y}{dx^2} = M,
\]

which is the required differential equation of the elastic curve.

In what follows the external bending moment \( M \) is assumed to be negative if it tends to revolve the portion of the beam under consideration in a clockwise direction, and positive if the revolution is counter-clockwise.
Problem 75. Find the equation of the elastic curve and the deflection at the center of a simple beam of length \( l \), bearing a single concentrated load \( P \) at its center.

Solution. The elastic curve in this case consists of two branches, \( AB \) and \( BC \) (Fig. 55).

Consider the portion of the beam on the left of any section \( mn \), distant \( x \) from the left support. Then \( M = -R_1 x = -\frac{P}{2} x \), and consequently the differential equation of the branch \( AB \) of the elastic curve is

\[
EI \frac{d^2y}{dx^2} = -\frac{Px}{2}.
\]

Integrating twice,

\[
EI \frac{dy}{dx} = -\frac{Px^2}{4} + C_1,
\]

and

\[
EI y = -\frac{Px^3}{12} + C_1 x + C_2.
\]

At \( B \), \( x = \frac{l}{2} \) and \( \frac{dy}{dx} = 0 \), since the tangent at \( B \) is horizontal. Substituting these values in the first integral, \( C_1 = \frac{Pl^2}{16} \). At \( A \), \( x = 0 \) and \( y = 0 \); hence \( C_2 = 0 \). Consequently, the equation of the left half of the elastic curve is

\[
y = \frac{Px}{48EI} \left( 3l^2 - 4x^2 \right).
\]

The deflection \( D \) at the center is the value of \( y \) for \( x = \frac{l}{2} \); hence

\[
D = \frac{Pl^4}{48EI}.
\]

Problem 76. Find the equation of the elastic curve and the maximum deflection for a cantilever of length \( l \), bearing a single concentrated load \( P \) at the end.

Problem 77. Find the equation of the elastic curve and the maximum deflection for a simple beam of length \( l \), bearing a single concentrated load \( P \) at a distance \( d \) from the left support.

Solution. The elastic curve in this case consists of two branches, \( AB \) and \( BC \) (Fig. 56). For a point in \( AB \) distant \( x \) from the left support, \( M = -\frac{P(l-d)x}{l} \). Therefore

\[
EI \frac{d^2y}{dx^2} = -\frac{P(l-d)x}{l}.
\]

Integrating twice,

\[
EI \frac{dy}{dx} = -\frac{P(l-d)x^2}{2l} + C_1,
\]

\[
EI y = -\frac{P(l-d)x^3}{6l} + C_1 x + C_2.
\]
and 
\[ EIy = -\frac{P(l - d) x^3}{6l} + C_1 x + C_2. \]

At \( A \), \( x = 0 \) and \( y = 0 \); therefore \( C_2 = 0 \). In order to determine \( C_1 \) it is necessary to find the equation of \( BC \).

Taking a section on the right of \( B \), \( M = -\frac{Pd(l - x)}{l} \), and consequently
\[ EI \frac{d^2y}{dx^2} = -\frac{Pd(l - x)}{l}. \]
Integrating twice,
\[ EI \frac{dy}{dx} = -\frac{Pd}{l} \left( lx - \frac{x^2}{2} \right) + C_3, \]
and
\[ EIy = -\frac{Pd}{l} \left( \frac{lx^2}{2} - \frac{x^3}{6} \right) + C_3 x + C_4. \]

At \( C \), \( x = l \) and \( y = 0 \); therefore \( C_4 = \frac{Pdl^3}{3} - C_3 l \).

Now at \( B \) both branches of the elastic curve have the same ordinate and the same slope. Therefore, putting \( x = d \) in the above integrals and equating the slopes and ordinates of the two branches,
\[ -\frac{P(l - d) d^2}{2l} + C_1 = -\frac{Pd}{l} \left( ld - \frac{d^2}{2} \right) + C_3, \]
\[ -\frac{P(l - d) d^3}{6l} + C_1 d = -\frac{Pd}{l} \left( \frac{ld^2}{2} - \frac{d^3}{6} \right) + C_3 d + \frac{Pdl^3}{3} - C_3 l. \]
Solving these two equations simultaneously for \( C_1 \) and \( C_3 \),
\[ C_1 = \frac{Pd}{6l} (2l - d)(l - d), \]
\[ C_3 = \frac{Pd}{6l} (2d^2 + d^2). \]
Substituting these values of \( C_1 \) and \( C_3 \) in the above integrals, the equation of the branch \( AB \) becomes, after reduction,
\[ y = \frac{Px(l - d)}{6EIl} \left( 2ld - d^2 - x^2 \right), \]
and the equation of \( BC \) becomes
\[ y = \frac{Pd(l - x)}{6EIl} \left( 2lx - d^2 - x^2 \right). \]

Since the load is not at the center of the beam, the maximum deflection will occur in the longer segment. Moreover, at the point of maximum deflection the tangent is horizontal, that is, \( \frac{dy}{dx} = 0 \). Therefore, equating to zero the first differential coefficient of the branch \( AB \),
\[ 0 = -\frac{P(l - d) x^2}{2l} + \frac{Pd}{6l} (2l - d)(l - d); \]
from which the distance of the point of maximum deflection from the left support is found to be

\[ x = \sqrt{\frac{d(2l - d)}{3}}, \]

and the deflection at this point is

\[ D = \frac{P(l - d)}{3EI} \left[ \frac{d(2l - d)}{3} \right]^3. \]

**Problem 78.** Find the equation of the elastic curve and the maximum deflection for a simple beam of length \( l \), bearing a uniform load of \( w \) lb. per unit of length.

**Problem 79.** Find the equation of the elastic curve and the maximum deflection for a cantilever of length \( l \), uniformly loaded with a load of \( w \) lb. per unit of length.

**Problem 80.** A Carnegie I-beam, No. B 13, is 10 ft. long and bears a load of 25 tons at its center. Find the deflection of the point of application of the load.

**Note.** From the Carnegie handbook, the moment of inertia of the beam about a neutral axis perpendicular to the web is \( I = 84.9 \text{ in.}^4 \).

**Problem 81.** Find the deflection of the beam in the preceding problem at a point 4 ft. from one end.

67. **Limitation to Bernoulli’s assumption.** In Article 39 it was stated that Bernoulli’s assumption formed the basis of the common theory of flexure. In the case of a prismatic beam subjected to pure bending strain, this assumption is rigorously correct. For if the opposite faces of a prism \( ABCD \) (Fig. 57) are acted upon by equal bending moments of opposite sign, both faces must, by reason of symmetry, remain plane and take a position such as \( A'B'C'D' \) in the figure.

However, if shearing stress also occurs, Bernoulli’s assumption is no longer absolutely correct. In Article 55 it was proved that the distribution of shear over any cross section limited by parallel sides varies as the ordinates to a parabola. Consequently, if the beam is supposed cut into thin layers by horizontal planes, as represented in
Fig. 58, the shear will tend to slide these layers one upon another. By Hooke's law, the amount of this sliding for different layers will also vary as the ordinates to a parabola, being zero at top and bottom and a maximum at the center. Therefore, if the elongations and contractions of the fibers due to bending stress are combined with the sliding due to shear, the resultant deformation of the prism will be as represented in Fig. 59.

**68. Effect of shear on the elastic curve.** In addition to the horizontal shearing stress acting at any point in a beam, there is a shearing stress of equal intensity acting in a vertical direction. The effect of this vertical shear is to slide each cross section past its adjacent cross section, as represented in Fig. 60, and thus increase the deflection of the beam.

In extended treatises on the strength of materials formulas are derived by means of which the amount of this shearing deflection can be calculated. It is found, however, that in all ordinary cases the shearing deflection is so small that it can be neglected, in comparison with the deflection due to bending strain. The point to be remembered, then, is that the shearing deflection is negligible but not zero.

In precise laboratory experiments for the determination of Young's modulus it should always be ascertained whether or not the shearing deformation can be neglected without affecting the precision of the result.

**69. Built-in beams.** If the ends of a beam are secured in such a way as to be immovable, the beam is said to be built-in. Examples of built-in beams are found in reinforced concrete construction, in which all parts are monolithic. Thus a floor beam in a building constructed of reinforced concrete is of one piece with its supporting girders, and consequently its ends are immovable.

Since the tangents at the ends of a built-in beam are horizontal, \( \frac{dy}{dx} = 0 \) at these points. Also, from Fig. 61, it is obvious that the
elastec curve of a built-in beam differs from that for a simple beam in having two points of inflection, \( A \) and \( B \). At these points the curvature is zero, that is, \( \frac{d^2y}{dx^2} = 0 \), and consequently the bending moment is also zero, since \( EI \frac{d^2y}{dx^2} = M \).

**Problem 82.** Find the equation of the elastic curve and the maximum deflection for a beam of length \( l \), fixed at both ends and bearing a uniform load of \( w \) lb. per unit of length.

**Solution.** Let \( M_a \) and \( M_b \) denote the moments at the supports (Fig. 62). The vertical reactions at the supports are each equal to \( \frac{wl}{2} \).

Consequently, the bending moment at a point distant \( x \) from the left support is

\[ M_x = M_a - \frac{wx^2}{2} + \frac{wx^2}{2}, \]

and therefore

\[ EI \frac{d^2y}{dx^2} = M_a - \frac{wx^2}{2} + \frac{wx^2}{2}. \]

Integrating,

\[ EI \frac{dy}{dx} = M_a x - \frac{wx^2}{4} + \frac{wx^3}{6} + C_1. \]

At \( A, x = 0 \) and \( \frac{dy}{dx} = 0 \); therefore \( C_1 = 0 \). At \( B, x = l \) and \( \frac{dy}{dx} = 0 \); therefore \( M_a = \frac{wl^2}{12} \). Substituting this value of \( M_a \) in the above integral, and integrating again,

\[ EI y = \frac{wl^2 x^2}{24} - \frac{wlx^3}{12} + \frac{wx^4}{24} + C_2. \]

At \( A, x = 0 \) and \( y = 0 \); therefore \( C_2 = 0 \). Consequently, the equation of the elastic curve is, after reduction,

\[ y = \frac{wx^2(l - x)^2}{24 EI}. \]
Putting \( x = \frac{l}{2} \) in this equation, the maximum deflection is found to be

\[
D = \frac{wx^4}{384EI}.
\]

At the points of inflection \( \frac{d^2y}{dx^2} = 0 \). Therefore

\[
0 = M_a - \frac{wx^2}{2} + \frac{wx^2}{2};
\]

whence

\[
x = \frac{l}{2} \pm \frac{l}{\sqrt{12}} = .212l \text{ or } .788l,
\]

which are the distances of the two points of inflection from the left support.

**Problem 83.** A beam of length \( l \) is fixed at both ends and bears a single concentrated load \( P \) at a distance \( d \) from the left end. Find the deflection at the point of application of the load.

**Problem 84.** From the result of Problem 83, find the deflection at the point of application of the load when the load is at the center.

**Problem 85.** A concrete girder 16 ft. long, 18 in. deep, and 12 in. wide is reinforced by two 1-in. twisted square steel rods near its lower face, and bears a uniform load of 250 lb. per linear inch. The moment of inertia of the equivalent homogeneous section about its neutral axis (Article 48) is found to be \( I_c = 7230 \text{ in.}^4 \). Find the maximum deflection.

**70. Continuous beams.** A continuous beam is one which is supported at several points of its length, and thus extends continuously over several openings. If the reactions of the several supports were known, the distribution of stress in the beam and the equation of the elastic curve could be found by the methods employed in the preceding articles. The first step, therefore, is to determine the unknown reactions. General methods for determining these will be explained in Articles 71, 77, 79, and 80. The two following problems illustrate special methods of treating the two simple cases considered.

**Problem 86.** A beam is simply supported at its center and ends, and bears a single concentrated load \( P \) at the center of each span. Assuming that the supports are at the same level, find their reactions and the equation of the elastic curve.

**Solution.** Let each span be of length \( l \), and assume the origin of coordinates at \( O \) (Fig. 63). Consider the portion of the beam on the right of a section \( ma \), distant \( x \) from \( O \). Then, if \( x < \frac{l}{2} \),

\[
EI \frac{d^2y}{dx^2} = P \left( \frac{l}{2} - x \right) - R_a(l - x).
\]
Integrating twice,

\[
EI \frac{dy}{dx} = P \left( \frac{lx}{2} - \frac{x^3}{2} \right) - R_3 \left( \frac{lx}{2} - \frac{x^3}{2} \right) + C_1,
\]

\[
EIy = P \left( \frac{lx^2}{4} - \frac{x^5}{6} \right) - R_3 \left( \frac{lx^2}{2} - \frac{x^5}{6} \right) + C_1x + C_2.
\]

At \( O \), \( x = 0 \) and \( \frac{dy}{dx} = 0 \); therefore \( C_1 = 0 \). Also at \( O \), \( x = 0 \) and \( y = 0 \); therefore \( C_2 = 0 \).

Let \( x \) be greater than \( \frac{l}{2} \). Then the differential equation of the branch \( AB \) becomes

\[
EI \frac{d^2y}{dx^2} = -R_3(l - x).
\]

Integrating,

\[
EI \frac{dy}{dx} = -R_3 \left( \frac{lx}{2} - \frac{x^3}{2} \right) + C_3.
\]

At \( A \) both branches, \( OA \) and \( AB \), have the same slope. Therefore, putting \( x = \frac{l}{2} \) in \((38)\) and \((40)\), and equating the values of \( \frac{dy}{dx} \) thus obtained,

\[
P \left( \frac{l^2}{4} - \frac{l^5}{8} \right) - R_3 \left( \frac{l^2}{2} - \frac{l^5}{8} \right) = -R_3 \left( \frac{l^2}{2} - \frac{l^5}{8} \right) + C_3;
\]

whence

\[C_3 = \frac{Pl^3}{8}.
\]

Substituting this value of \( C_3 \) in equation \((40)\), and integrating again,

\[
EIy = -R_3 \left( \frac{lx^2}{2} - \frac{x^5}{6} \right) + \frac{Pl^2x}{8} + C_4.
\]

At \( A \) both curves have the same ordinate. Therefore, putting \( x = \frac{l}{2} \) in equations \((39)\) and \((41)\), and equating the values of \( y \) thus obtained,

\[
P \left( \frac{l^3}{16} - \frac{l^5}{48} \right) - R_3 \left( \frac{l^3}{8} - \frac{l^5}{48} \right) = -R_3 \left( \frac{l^3}{8} - \frac{l^5}{48} \right) + \frac{Pl^3}{16} + C_4;
\]
whence
\[ C_4 = -\frac{P l^3}{48}. \]

The equations of both branches of the elastic curve are now determined except that the reaction \( R_3 \) is still unknown. Since \( B \) is assumed to be on the same level with \( O \), its ordinate is zero. Therefore, to determine \( R_3 \), put \( x = l \) and \( y = 0 \) in equation (41); whence
\[ R_3 = \frac{1}{4} P. \]

From symmetry \( R_1 = R_3 \). Therefore
\[ R_2 = 2P - (R_1 + R_3) = \frac{1}{4} P. \]

**Problem 87.** Determine the reactions of the supports for a beam simply supported at its center and ends, and bearing a uniform load of \( w \) lb. per unit of length.

**Solution.** If the end supports were removed, the beam would consist of two cantilevers, \( AB \) and \( BC \) (Fig. 64), each of length \( l \) and bearing a uniform load.

From Problem 66, the deflection at the end of such a beam is \( D = \frac{w l^4}{8EI} \). But the reaction \( R_3 \) (or \( R_1 \)) must be of such amount as to counteract this deflection; and, from Problem 76, the deflection at the end of a cantilever bearing a single concentrated load \( R_3 \) is \( D = \frac{R_3 l^3}{3EI} \). Therefore
\[ \frac{R_3 l^3}{3EI} = \frac{w l^4}{8EI}; \]
whence
\[ R_3 = \frac{1}{8} w l. \]

From symmetry, \( R_1 = R_3 \). Consequently,
\[ R_2 = 2wl - (R_1 + R_3) = \frac{1}{4}wl. \]

Having found the reactions of the supports, the equations of the elastic curves can be determined as in the preceding problems.

**71. Theorem of three moments.** The theorem of three moments is an algebraic relation between the bending moments at three consecutive piers of a continuous beam. The theorem is due to Clapeyron,
and first appeared in the *Comptes Rendus* for December, 1857. The following is a simplified proof of the theorem for the case of uniform loading.

Let $A$, $B$, $C$ be three consecutive piers of a continuous beam at the same height, and let $M_a$, $M_b$, $M_c$ and $R_a$, $R_b$, $R_c$ denote the bending moments and reactions at these three points respectively (Fig. 65).

Also, let $l_1$ and $l_2$ denote the lengths of the two spans considered, and $w_1$, $w_2$ the unit loads on them. Then, taking $A$ as origin, the differential equation of $AB$ is

\[ (42) \quad EI \frac{d^2y}{dx^2} = M_a + R_a x - \frac{w_1 x^2}{2}. \]

Integrating twice,

\[ (43) \quad EI \frac{dy}{dx} = M_a x + R_a \frac{x^2}{2} - \frac{w_1 x^3}{6} + C_1, \]

and

\[ EI y = M_a \frac{x^2}{2} + R_a \frac{x^3}{6} - \frac{w_1 x^4}{24} + C_1 x + C_2. \]

At $A$, $x = 0$ and $y = 0$; hence $C_2 = 0$. At $B$, $x = l_1$ and $y = 0$; hence

\[ C_1 = -\frac{1}{2} M_a l_1 - \frac{1}{6} R_a l_1^2 + \frac{w_1 l_1^3}{24}. \]

In equation (42), if $x = l_1$, $EI \frac{d^2y}{dx^2} = M_b$. Therefore

\[ (44) \quad M_b = M_a + R_a l_1 - \frac{w_1 l_1^3}{2}. \]

If $\frac{dy}{dx}_b$ denotes the slope of the elastic curve $AB$ at $B$, then, from equation (43),
Similarly, by taking the origin at \( C \) and reckoning backward toward \( B \), it will be found that

\[
M_b = M_c + R_c l_2 - \frac{w_2 l_2^2}{2},
\]

and

\[
-EI \frac{dy}{dx}_b = \frac{1}{2} M_c l_2 + \frac{1}{3} R_c l_2^2 - \frac{w_2 l_2^2}{8}.
\]

Equating the values of \( \frac{dy}{dx}_b \) from equations (45) and (47), and eliminating \( R_a \) and \( R_c \) from the resulting equation by means of equations (44) and (46),

\[
\frac{1}{2} M_a l_1 + \left( \frac{1}{3} M_b l_1 - \frac{1}{3} M_a l_1 + \frac{w_1 l_1^3}{6} \right) - \frac{w_1 l_1^3}{8} = -\frac{1}{2} M_c l_2 - \left( \frac{1}{3} M_b l_2 - \frac{1}{3} M_c l_2 + \frac{w_2 l_2^3}{6} \right) + \frac{w_2 l_2^3}{8};
\]

whence

\[
M_a l_1 + 2 M_b (l_1 + l_2) + M_c l_2 = -\frac{w_1 l_1^3 + w_2 l_2^3}{4},
\]

which is the required theorem of three moments.

If the beam extends over \( n \) supports, this theorem furnishes \( n - 2 \) equations between the \( n \) moments at the supports, the remaining two equations necessary for solution being furnished by the terminal conditions at the ends of the beam.

**Problem 88.** A continuous beam of two equal spans bears a uniform load extending continuously over both spans. Find the bending moments and reactions at the supports.

**Solution.** In the present case \( w_1 = w_2 = w \), \( l_1 = l_2 = l \), and \( M_a = M_c = 0 \). Consequently, the theorem reduces to

\[
2 M_b (2 l) = -\frac{2 w l^2}{4};
\]

whence

\[
M_b = -\frac{w l^2}{8}.
\]

From equation (44),

\[
-\frac{w l^2}{8} = R_a l - \frac{w l^2}{2};
\]

whence

\[
R_a = \frac{3}{8} w l.
\]
From symmetry, \( R_a = R_c \), and consequently
\[
R_b = \frac{1}{3} wl.
\]

**Problem 89.** A continuous beam of four equal spans is uniformly loaded. Find the bending moments and reactions at the supports.

**Solution.** The system of simultaneous equations to be solved in this case is
\[
egin{align*}
M_1 &= 0, \\
M_1 + 4M_2 + M_3 &= -\frac{wl^2}{2}, \\
M_2 + 4M_3 + M_4 &= -\frac{wl^2}{2}, \\
M_3 + 4M_4 + M_5 &= -\frac{wl^2}{2}, \\
M_5 &= 0,
\end{align*}
\]
the solution of which gives
\[
egin{align*}
M_2 &= M_4 = -\frac{1}{8} wl^2, & M_3 &= -\frac{1}{4} wl^2, \\
R_1 &= R_5 = \frac{1}{4} wl, & R_2 &= R_4 = \frac{1}{8} wl, & R_3 &= \frac{1}{6} wl.
\end{align*}
\]

**Problem 90.** A continuous beam of five equal spans is uniformly loaded. Find the moments and reactions at the supports.

72. **Work of deformation.** In changing the shape of a body the points of application of the external forces necessarily move, and therefore do a certain amount of work called the work of deformation.

To find the amount of this work of deformation for a prismatic beam, consider two adjacent cross sections of the beam at a distance \( dx \) apart (Fig. 66). Suppose one of these cross sections remains stationary and the other turns through an angle \( d\beta \) with reference to the first. Then the change in length of a fiber at a distance \( y \) from the neutral axis is \( yd\beta \), and therefore, by Hooke's law,
\[
\frac{yd\beta}{dx} = \frac{p}{E},
\]
where \( p \) is the intensity of the stress on the fiber. By the straight-line law, \( p = \frac{My}{I} \), and hence
\[
d\beta = \frac{Mdx}{EI}.
\]
Since one of the cross sections is assumed to be stationary, the stress acting on it does no work. On the other cross section the normal
stress forms a moment equal to \( M \). This moment is zero when first applied, and gradually increases to its full value, its average value being \( \frac{1}{2} M \). Therefore the work done by the normal stress on this cross section is

\[
dW = \frac{1}{2} M d\beta = \frac{M^2 dx}{2 EI}
\]

Hence the total work of deformation for the entire beam is

\[
W = \frac{1}{2} \int \frac{M^2 dx}{EI}.
\]

**Problem 91.** As an application of the above, find the deflection at the center of a simple beam of length \( l \), bearing a single concentrated load \( P \) at the center.

**Solution.** Let \( D \) denote the deflection at the center. Then the external work of deformation is

\[
W = \frac{1}{4} PD.
\]

At a point distant \( z \) from the left support the bending moment is \( M = \frac{Pz}{2} \), and consequently the internal work of deformation is

\[
W = \int_0^l \frac{\left( \frac{Pz}{2} \right)^2 dx}{EI} = \frac{P^2 l^3}{96 EI}.
\]

Therefore

\[
\frac{1}{2} PD = \frac{P^2 l^3}{96 EI};
\]

whence

\[
D = \frac{Pl^3}{48 EI}.
\]

**Problem 92.** Find the internal work of deformation for a rectangular wooden beam 10 ft. long, 10 in. deep, and 8 in. wide, which bears a uniform load of 250 lb. per foot of length.

**73. Impact and resilience.** In the preceding article an expression was deduced for the work done by the stress in producing deformation of a beam. If the stress lies within the elastic limit of the material, the body returns to its original shape upon removal of the external forces, and the internal work of deformation is given out again in the form of mechanical energy. The internal work of deformation is thus a form of potential energy, and from this point of view is called **resilience**.

The work done in straining a unit volume of a material to the elastic limit is called the **modulus of resilience** of the material.
When a load is suddenly applied to a beam, as when a body falls on the beam, or in the case of a railway train passing quickly over a girder, the deflection of the beam is much greater than it would be if the load was applied gradually, for in this case the full amount of the load is applied at the start instead of gradually increasing from zero up to this amount. Since the load is not sufficiently great to cause the beam to retain this deflection, the resilience of the beam causes it to vibrate back and forth until the effect of the shock dies away. The sudden application of a load is called impact, and the study of its effect is of especial importance in designing machines, railway bridges, or any construction liable to shocks.

If a simple beam deflects an amount \( D \) under a load \( P \) suddenly applied, the work of deformation is \( PD \). If the beam deflects the same amount under a load \( P' \) gradually applied, the work of deformation is \( \frac{1}{2} P'D \). Hence

\[
P' = 2P.
\]

In other words, the strain produced in a beam by a load applied suddenly is equivalent to the strain produced by a load twice as great applied gradually. In practical work \( P' \) is assumed to be about \( \frac{3}{2} P \) instead of \( 2P \), for it is impossible to apply a load instantaneously at the most dangerous section.

If a body of weight \( P \) falls on a beam from a height \( h \) and produces a deflection \( D \), the work done by \( P \) is \( P(h + D) \). Therefore, if \( P' \) is the amount of a static load which would produce the same deflection,

\[
\frac{1}{2} P'D = P(h + D).
\]

In order to find \( P' \) from this equation \( D \) must be expressed in terms of \( P' \) and its value substituted in the above expression before solving for \( P' \).

Problem 93. A Cambria steel I-beam, No. B 33, is 12 ft. long and 10 in. deep, and has a moment of inertia about an axis perpendicular to the web of 122.1 in.\(^4\). What is the maximum load that can fall on the center of the beam from a height of 6 in. without producing a stress greater than 25,000 lb./in.\(^2\), if 75 per cent of the kinetic energy of the falling body is transformed into work of deformation?

Solution. Let \( P \) denote the weight of the falling body and \( P' \) the amount of a static load which would produce the same work of deformation. Then, since the moment at the center of the beam is \( M = \frac{P'l}{4} \), \( p = \frac{Me}{I} = \frac{P'le}{4I} \), whence \( P' = \frac{4p'l}{le} \).
The deflection of a beam bearing a static load \( P' \) at the center is \( D = \frac{P'^3}{48EI} \) (Problem 75), or, substituting in this the value of \( P' \), \( D = \frac{P'^3l^2}{12Ee} \). Assuming \( E = 30,000,000 \) lb./in.\(^2\), and replacing \( p \), \( l \), and \( e \) by the values given in the problem, 
\[
D = .288 \text{ in.}
\]
Consequently, the work of deformation is
\[
W = \frac{1}{2} P'D = \frac{P'^2ll}{6Ee^2} = 2442 \text{ in. lb.}
\]
Therefore, from the equality \( \frac{1}{2} P'D = P(h + D) \), we have
\[
2442 = .75P(6 + .288);
\]
whence
\[
P = 518 \text{ lb.}
\]
Problem 94. From what height can a weight of half a ton fall on the middle of the beam in the preceding problem without producing a stress greater than 40,000 lb./in.\(^2\) ?

74. * Influence line for bending moment. As a load moves over a structure the bending moment and shear at any given point change continuously. This variation of the bending moment, shear, or any similar function at a given fixed point due to a moving load can be represented graphically by a curve (or straight line) called an influence line.

To obtain the influence line for bending moment for a simple beam of length \( l \), let \( d \) denote the distance of the given point \( A \) from the left support \( O \), and \( x \) the distance of a movable load \( P \) from \( O \) (Fig. 67). Then, if \( P \) is on the right of \( A \), \( R_1 = \frac{P(l - x)}{l} \), and hence the moment at \( A \) is
\[
M_a = \frac{P(l - x)d}{l}.
\]
Now let \( P \) be a unit load (say one pound or one ton). Then
\[
M_a = \frac{(l - x)d}{l};
\]
* For a brief course the remainder of this chapter may be omitted.
and if the values of \( M_a \) corresponding to each value of \( x \) from \( d \) to \( l \) are laid off as ordinates, we obtain the straight line \( A'B' \), which therefore represents the variation in the bending moment at the point \( A \) as the unit load moves from \( B \) to \( A \). Similarly, if the unit load is on the left of \( A \), \( M_a = \frac{x(l-d)}{l} \), which is the equation of the straight line \( O'A' \). At \( D' \) both lines have the same ordinate, namely, \( A'E = \frac{d(l-d)}{l} \). The influence line for bending moment is therefore the broken line \( O'A'B' \).

From this construction, it is obvious that the ordinate to the influence line at any point \( D \) represents the bending moment at \( A \) due to a unit load at \( D \). Thus, as a unit load comes on the beam from the right, the bending moment at \( A \) increases from the value zero for the load at \( B \) to the value \( A'E \) for the load at \( A \), and then decreases again to the value zero at \( O \). Therefore, having constructed for a unit load the influence line corresponding to any given point \( A \), the moment at \( A \) due to a load \( P \) is found by multiplying \( P \) by the ordinate to the influence line directly under \( P \).

**Problem 95.** Find the position of a system of moving loads on a beam so that the bending moment at any point \( A \) shall be a maximum.

**Solution.** Let \( O'A'B' \) be the influence line for bending moment for the point \( A \), and let the loads on each side of \( A \) be replaced by their resultants \( P_1 \) and \( P_2 \) (Fig. 68). Then, if \( y_1 \) and \( y_2 \) are the ordinates to the influence line directly under \( P_1 \) and \( P_2 \), the moment at \( A \) is

\[
M_a = P_1 y_1 + P_2 y_2.
\]

Now, if the loads move a small distance \( dx \) to the left, the moment at \( A \) becomes

\[
M_a + dM_a = P_1 (y_1 - dx \tan \alpha) + P_2 (y_2 + dx \tan \beta).
\]

Therefore, by subtraction,

\[
dM_a = -P_1 dx \tan \alpha + P_2 dx \tan \beta,
\]

and hence

\[
\frac{dM_a}{dx} = -P_1 \tan \alpha + P_2 \tan \beta.
\]
For a maximum value of \( M_a \), \( \frac{dM_a}{dx} = 0 \), in which case

\[
P_2 \tan \beta = P_1 \tan \alpha.
\]

This equation may be written

\[
P_2 \frac{A'C'}{C'B'} = P_1 \frac{A'C'}{O'C'},
\]

or

\[
\frac{P_2}{C'B'} = \frac{P_1}{O'C'},
\]

from which, by composition,

\[
\frac{P_1 + P_2}{O'B'} = \frac{P_1}{O'C'},
\]

which is the criterion for maximum moment at \( A \). Expressed in words, the moment at any point \( A \) is a maximum when the unit load on the whole span is equal to the unit load on the smaller segment.

75. Influence line for shear. To obtain the influence line for shear, let \( l, d, \) and \( x \) have the same meaning as in the preceding article. The shear at any point \( A \) is equal to the reaction at \( O \), and for a unit load this reaction is

\[
R_1 = \frac{l - x}{l}.
\]

If, then, the values of \( R_1 \) for all values of \( x \) from \( d \) to \( l \) are laid off as ordinates, the locus of their ends will be the straight line \( B'A' \) (Fig. 69). Similarly, for a unit load on the left of \( A \) the shear at \( A \) is negative, and its amount is \(- R_2 = - \frac{x}{l}\), which is the equation of the straight line \( O'A'' \). Since the slopes of the two lines \( A'B' \) and \( O'A'' \) are equal, these lines are parallel. The influence line for shear is, then, the broken line \( O'A''A'B' \).

As a load comes on the beam from the right the shear at \( A \) gradually increases from the value zero for the load at \( B \) to the value \( A'E \) for the load just to the right of \( A \). As the load passes \( A \) the shear at this point suddenly decreases by the amount of the load, thus becoming negative, and then increases until the load reaches \( O \), when it again becomes zero. Consequently, the shear at \( A \), due to a load \( P \) at
any point \( C \), is found by multiplying \( P \) by the ordinate to the influence line at \( C' \), directly under \( C \).

**Problem 96.** Find the position of a system of moving loads on a beam so that the shear at any point \( A \) shall be a maximum.

**Solution.** Let the influence line for the point \( A \) be as represented in Fig. 70. Also let \( P_1 \) and \( P_2 \) be two consecutive loads, \( d \) the distance between them, and \( P' \) the resultant of all the loads on the beam. Since \( A' E \) is the maximum ordinate to the influence line, the maximum shear at \( A \) must occur when one of the loads is just to the right of \( A \). Suppose the load \( P_1 \) is just to the right of \( A \). Then as \( P_1 \) passes \( A \) the shear at \( A \) is suddenly decreased by the amount \( P_1 \). If the loads continue to move to the left until \( P_2 \) reaches \( A \), the shear is gradually increased by the amount \( P'd \tan \alpha \), since the ordinate under each load is increased by the amount \( d \tan \alpha \). Consequently, either \( P_1 \) or \( P_2 \) at \( A \) will give the maximum shear at this point according as

\[
P_1 \geq P'd \tan \alpha;
\]

or, since \( \tan \alpha = \frac{1}{d} \), according as

\[
\frac{P_1}{d} \geq \frac{P'}{l}.
\]

By means of this criterion, it can be determined in any given case which of two consecutive loads will give the greater shear at any point.

**76. Maxwell's theorem.** When a load is brought on a beam it causes every point of the beam to deflect, the amount of this deflection for any point being the corresponding ordinate to the elastic curve. If, then, a number of loads rest on a beam, the deflection at any point of the beam is the sum of the deflections at this point due to each of the loads taken separately.

For example, if two loads \( P_1 \) and \( P_2 \) rest on a beam at the points \( A \) and \( B \) respectively, the deflection at one of these points, say \( A \), is composed of two parts, namely, the deflection at \( A \) due to \( P_1 \) and the deflection at \( A \) due to \( P_2 \). Similarly, the total deflection at \( B \) is composed of the partial deflections due to \( P_1 \) and \( P_2 \) respectively.
Maxwell's theorem, when modified so as to apply to beams, states that if unit loads rest on a beam at two points $I$ and $K$, the deflection at $I$ due to the unit load at $K$ is equal to the deflection at $K$ due to the unit load at $I$. The following simple proof of the theorem is due to Föppl.*

Consider a simple beam bearing unit loads at two points $I$ and $K$ (Fig. 71). Let the deflection at $K$ due to a unit load at $I$ be denoted by $J_{ik}$, the deflection at $I$ due to a unit load at $I$ by $J_{ii}$, etc., the second subscript in each case denoting the point at which the unit load is applied, and the first subscript the point for which the number gives the deflection. Thus $J_{ik}$ denotes the influence of a unit load at $K$ on the deflection at $I$. For this reason the quantity $J_{ik}$ is called an influence number.

If the load at $I$ is of amount $P_i$, the deflection at $I$ is $J_{ii}P_i$, that at $K$ is $J_{ki}P_i$, etc.

Now suppose that a load $P_i$ is brought on the beam gradually at the point $I$. Then its average value is $\frac{1}{2}P_i$, the deflection under the load is $J_{ii}P_i$, and consequently the work of deformation is $\frac{1}{2}P_i(J_{ii}P_i)$. After the load $P_i$ attains its full value suppose that a load $P_k$ is brought on gradually at $K$. Then the average value of this load is $\frac{1}{2}P_k$, but since $P_i$ keeps its full value during this second deflection, the work of deformation in this movement is $P_i(J_{ik}P_k) + \frac{1}{2}P_k(J_{kk}P_k)$. Therefore the total work of deformation from both deflections is

$$W = \frac{1}{2}J_{ii}P_i^2 + J_{ik}P_iP_k + \frac{1}{2}J_{kk}P_k^2.$$  

Evidently the same amount of work would have been done if the load $P_k$ had first been applied, and then $P_i$. The expression for the total work obtained by applying the loads in this order is

$$W = \frac{1}{2}J_{ik}P_iP_k + J_{kk}P_kP_k + \frac{1}{2}J_{ii}P_i^2.$$  

Therefore, equating the two expressions for the work of deformation,

$$J_{ik} = J_{ki},$$

which proves the theorem.

*Festigkeitslehre, p. 197.
Problem 97. A beam bears a load of 15 tons at a certain point A, and its deflections at three other points, B, C, D, are measured and found to be .30 in., .15 in., and .00 in. respectively. If loads of 5, 12, and 8 tons are brought on at B, C, and D respectively, find the deflection at A.

Solution. The deflections at B, C, and D due to a unit load (one ton) at A are $\frac{.30}{15} = .02$ in., $\frac{.15}{15} = .01$ in., and $\frac{.00}{15} = .006$ in. respectively. Therefore, by Maxwell's theorem, the deflection at A is

$$D_a = .02 \times 5 + .01 \times 12 + .006 \times 8 = .268 \text{ in.}$$

77. Influence line for reactions. The most important application of Maxwell's theorem is to the determination of the unknown reactions for a continuous beam.

Consider a beam continuous over three supports, as shown in Fig. 72. Suppose the middle support removed and a unit load (say 1 ton) placed at this point. Then, if the elastic curve is plotted, the ordinate to this curve at any point I is the deflection at I due to the unit load at B, or, in other words, this ordinate is the influence number $J_{ib}$. Similarly, the ordinate to the elastic curve at B is the influence number $J_{bb}$.

Now $R_2$, the unknown reaction at B, must be of such amount as to counteract the deflection at B due to a load P at any point I. Therefore

$$R_2 J_{bb} = P J_{bi}.$$

But, by Maxwell's theorem, $J_{bi} = J_{ib}$; consequently

$$R_2 = P \left( \frac{J_{ib}}{J_{bb}} \right).$$

The influence numbers $J_{ib}$ and $J_{bb}$ are known as soon as the elastic curve for unit load at B is plotted. Therefore, in this case, the construction of one elastic curve gives sufficient data for all further calculations.
Since for any point $I$ the fraction $\frac{J_{ib}}{J_{bb}}$ is proportional to $J_{ib}$ (the denominator being constant), the elastic curve is called the influence line for reactions.

For a number of concentrated loads $P_1, P_2, \ldots, P_n$ the same method applies, $R_2$ in this case being given by the equation

$$R_2 = \frac{J_{1b}}{J_{bb}} P_1 + \frac{J_{2b}}{J_{bb}} P_2 + \cdots + \frac{J_{nb}}{J_{bb}} P_n,$$

or, more briefly,

$$R_2 = \frac{1}{J_{bb}} \sum_{i=1}^{n} J_{ib} P_i.$$

To determine the reactions for a beam continuous over four supports and bearing a single concentrated load $P$ at any point $I$, suppose the two middle supports removed. Then if a unit load is placed at $B$ (Fig. 73) and the elastic curve drawn, the ordinate to this curve at any point $I$ is the influence number $J_{ib}$. Similarly, by placing a unit load at $C$ and constructing the corresponding elastic curve, the influence number $J_{ic}$ is obtained. Now the reaction $R_2$ must be of such amount as to counteract the deflections at $B$ due to a load $P$ at $I$ and a load $R_3$ at $C$. Therefore

$$R_2 J_{ib} = P J_{bi} - R_3 J_{bc}.\tag{73}$$

Similarly the reaction $R_3$ must be of such amount as to counteract the deflections at $C$ due to a load $P$ at $I$ and a load $R_2$ at $B$. Therefore

$$R_3 J_{ic} = P J_{ci} - R_2 J_{cb}.$$
78. Castigliano's theorem. Consider a beam bearing any number of concentrated loads $P_1, P_2, \ldots, P_n$, acting either vertically upward or downward, and let $W$ denote the work of deformation due to these loads (Fig. 74). Then if one of the loads, say $P_i$, is increased by a small amount $dP_i$, the deflection of $P_i$ is increased by the amount $J_i dP_i$, that of $P_2$ by the amount $J_2 dP_i$, etc., where $J_{1i}, J_{2i}, \text{etc.}$, are influence numbers. Therefore the work of deformation is increased by the amount
\[
dW = P_1 J_{1i} dP_i + P_2 J_{2i} dP_i + \cdots + P_n J_{ni} dP_i;
\]
whence
\[
\frac{dW}{dP_i} = P_1 J_{1i} + P_2 J_{2i} + \cdots + P_n J_{ni}.
\]

In forming this expression the work done by $dP_i$ itself has been neglected, since it is infinitesimal in comparison with that done by $P_1, P_2, \text{etc.}$.

Now, from Maxwell's theorem, $J_{ik} = J_{ki}$. Therefore the above expression becomes
\[
\frac{dW}{dP_i} = P_1 J_{1i} + P_2 J_{2i} + \cdots + P_n J_{ni}.
\]
The right member of this equality, however, is the total deflection $D_i$ at the point $I$, due to all the loads. Consequently the above expression may be written
\[
\frac{dW}{dP_i} = D_i.
\]
Since the work of deformation $W$ is a function of all the loads and not of $P_i$ only, this latter expression should be written as a partial derivative; thus
\[
\frac{\partial W}{\partial P_i} = D_i,
\]
and in this form it is the algebraic statement of Castigliano's theorem. Expressed in words, the theorem is: The deflection of the point of application of an external force acting on a beam is equal to the partial derivative of the work of deformation with respect to this force.
79. Application of Castigliano's theorem to continuous beams.

Castigliano's theorem affords still another means of determining the unknown reactions of a continuous beam; for the reactions may be included among the loads on the beam, and since the points of application of these reactions are assumed to be fixed, their deflections are zero. Therefore, if $P_k$ is one of the reactions, $D_k = 0$, and consequently

$$\frac{\partial W}{\partial P_k} = 0.$$ 

A condition equation of this kind can be found for each reaction, and from the system of simultaneous equations so obtained the unknown reactions may be calculated. The following problems illustrate the application of the theorem.

Problem 98. A uniformly loaded beam of length $2l$ is supported at its center and ends. Find the reactions of the supports by means of Castigliano's theorem.

Solution. Let $w$ denote the unit load on the beam (Fig. 75).

From symmetry, $P_1 = P_3$. Also, by taking moments about $B$,

$$P_1 = wL - \frac{P_2}{2} = P_3.$$ 

For a point in the first opening at a distance $x$ from the left support,

$$M = P_1 x - \frac{wx^2}{2};$$

consequently,

$$W = \frac{1}{2} \int_0^l M^2 dx = \frac{1}{2} \frac{EI}{P_3} \left[ \frac{P_1 l^3}{3} - \frac{P_1 wL^4}{4} + \frac{w^2 l^5}{20} \right].$$

The work of deformation for the other half of the beam is of the same amount. Therefore the total work of deformation is

$$W = \frac{1}{EI} \left[ \frac{P_1 l^3}{3} - \frac{P_1 wL^4}{4} + \frac{w^2 l^5}{20} \right].$$

Since $P_1$ is a function of $P_3$, the partial derivative of $W$ with respect to $P_2$ is

$$\frac{\partial W}{\partial P_2} = \frac{1}{EI} \left[ 2 \frac{P_1 l^3}{3} \cdot \frac{\partial P_1}{\partial P_2} \ . \ P_1 + \frac{wL^4}{4} \cdot \frac{\partial P_1}{\partial P_2} \right].$$

Since $P_1 = wL - \frac{P_2}{2}$, $\frac{\partial P_1}{\partial P_2} = -\frac{1}{2}$. 

FIG. 75
Therefore
\[ \frac{\partial W}{\partial P_2} = \frac{l^3}{EI} \left[ \frac{wl}{8} - \frac{P_1}{3} \right]. \]

By Castigliano's theorem, \( \frac{\partial W}{\partial P_2} = 0 \). Therefore
\[ \frac{l^3}{EI} \left[ \frac{wl}{8} - \frac{P_1}{3} \right] = 0; \]
whence
\[ P_1 = \frac{1}{3} \frac{wl}{l}. \]

Substituting in this expression the value of \( P_1 \) in terms of \( P_2 \),
\[ P_2 = \frac{1}{3} \frac{wl}{l}. \]

**Problem 99.** A uniformly loaded beam extends over three openings of equal span. Find the reactions at the supports.

**Solution.** Let \( l \) denote the length of each span and \( w \) the unit load (Fig. 76).

From symmetry, \( P_1 = P_4 \) and \( P_2 = P_3 \). Also, by taking moments about \( B \),
\[ P_1 = \frac{3}{2} \frac{wl}{l} - P_2 = P_4. \]

For any point in the first opening at a distance \( x \) from the left support,
\[ M = P_1x - \frac{wx^2}{2}, \]
and therefore, as in the preceding problem,
\[ W_1 = \frac{1}{2EI} \left[ \frac{P_1l^3}{3} - \frac{P_1wl^4}{4} + \frac{wl^4}{20} \right]. \]

Since \( P_1 = P_4 \), \( W \) has the same value for the third opening, that is, \( W_3 = W_1 \). In the second opening
\[ M = P_1x + P_2(x - l) - \frac{wx^2}{2}, \]
and therefore
\[ W_2 = \frac{1}{2EI} \int_0^{l_2} \left( P_1x + P_2(x - l) - \frac{wx^2}{2} \right)^2 \, dx. \]

Hence the total work of deformation for all three openings is
\[ W = \frac{1}{2EI} \left\{ 3 P_1l^3 - \frac{17 P_1wl^4}{4} + \frac{33 w^2 l^2}{20} + \frac{5 P_1 P_2 l^3}{3} + \frac{P_2^2 l^3}{3} - \frac{17 P_2wl^4}{12} \right\}. \]

Therefore
\[ \frac{\partial W}{\partial P_2} = \frac{1}{2EI} \left\{ 6 P_1l^3 \frac{\partial P_1}{\partial P_2} - \frac{17 w^2 l^2}{4} \frac{\partial P_1}{\partial P_2} + \frac{5 P_1 P_2 l^3}{3} + \frac{P_2^2 l^3}{3} \frac{\partial P_1}{\partial P_2} + \frac{2 P_2 l^3}{3} - \frac{17 w^2 l^2}{12} \right\}. \]
Since \( P_1 = \frac{3wl}{2} - P_2 \), \( \frac{\partial P_1}{\partial P_2} = -1 \), and hence

\[
\frac{\partial W}{\partial P_2} = \frac{1}{2EI} \left\{ -\frac{13}{3} P_1 l^3 + \frac{17}{6} w l^4 - P_2 l^3 \right\}.
\]

Putting \( \frac{\partial W}{\partial P_2} = 0 \), and substituting for \( P_1 \) its value in terms of \( P_2 \),

\[
-\frac{13}{3} \left( \frac{3wl}{2} - P_2 \right) + \frac{17}{6} w l^4 - P_2 l^3 = 0;
\]

whence

\[
P_2 = \frac{4}{3}wl,
\]

and consequently

\[
P_1 = \frac{1}{3}wl.
\]

80. Principle of least work. Differentiating partially with respect to \( P_i \) both members of the equation \( \frac{\partial W}{\partial P_i} = D_i \), we have

\[
\frac{\partial^2 W}{\partial P_i^2} = \frac{\partial D_i}{\partial P_i}.
\]

As the load increases the deflection increases, and vice versa. Therefore, since \( \partial D_i \) and \( \partial P_i \) have the same sign, \( \frac{\partial D_i}{\partial P_i} \) is positive and hence \( \frac{\partial^2 W}{\partial P_i^2} \) is also positive. But, from the differential calculus,

\[
\frac{\partial W}{\partial P_i} = 0 \quad \text{and} \quad \frac{\partial^2 W}{\partial P_i^2} > 0
\]

are the conditions that \( W \) shall be a minimum. Consequently, the reactions of a continuous beam, calculated from the condition \( \frac{\partial W}{\partial P_i} = 0 \), are such that they make the work of deformation a minimum.

In Article 73 it was pointed out that the internal work of deformation is a form of potential energy. The above is thus a special case of what is known as the principle of least work, the general statement of this principle being: *For stable equilibrium the potential energy of any system is a minimum.*
Problem 100. Three Carnegie I-beams, No. B 80, are placed 4 ft. apart across
an opening 25 ft. wide. Across their centers is placed another I-beam of the same
dimensions as the first, and upon the center of this cross beam there rests a load of
10 tons. Find the greatest stress which occurs in any member of the construction.

Solution. Let the amount of the load at H, which is carried by GK, be denoted
by P (Fig. 77). Then the loads on AB and EF at G and K respectively are each
equal to \( \frac{P}{2} \), and the load on CD is 20,000 lb. - \( P \).

Now the work of deformation for a simple beam of length \( l \) bearing a single con-
centrated load \( P \) at its center is, from Problem 91,

\[
W = \frac{P^2l^3}{96EI}.
\]

Therefore, since the load on AB or EF is \( \frac{P}{2} \), the work of deformation for either
of these beams is

\[
W_{ab} = W_{ef} = \frac{P^2l_1^3}{384EI}.
\]

Similarly the work of deformation for CD is

\[
W_{cd} = \frac{(20,000 - P)^2l_3^3}{96EI},
\]

and for GK is

\[
W_{gk} = \frac{P^2l_2^3}{96EI}.
\]

Hence the total work of deformation for the entire construction is

\[
W = \frac{P^2l_1^3}{192EI} + \frac{(20,000 - P)^2l_3^3}{96EI} + \frac{P^2l_2^3}{96EI}.
\]

By the principle of least work, \( \frac{\partial W}{\partial P} = 0 \); consequently

\[
\frac{\partial W}{\partial P} = \frac{Pl_1^3}{96EI} - \frac{(20,000 - P)l_3^3}{48EI} + \frac{Pl_2^3}{48EI} = 0.
\]

From the Carnegie handbook, \( I = 795.6 \text{ in.}^4 \), and from the figure, \( l_1 = 300 \text{ in.} \),
\( l_2 = 96 \text{ in.} \). Inserting these numerical values in the above expression, and solving
for \( P \),

\[ P = 13,048 \text{ lb.} \]

Having determined \( P \), the stress in the various members can easily be calcu-
lated. Thus it is found that the greatest stress occurs in CD, its amount being
\( p = 23,593 \text{ lb./in.}^2 \).
CHAPTER V

COLUMNS AND STRUTS

81. Nature of compressive stress. When a prismatic piece of length equal to several times its breadth is subjected to axial compression it is called a column, or strut, the word "column" being used to designate a compression member placed vertically and bearing a static load; all other compression members being called struts.

If the axis of a column or strut is not perfectly straight, or if the load is not applied exactly at the centers of gravity of its ends, a bending moment is produced which tends to make the column deflect sideways, or "buckle." The same is true if the material is not perfectly homogeneous, causing certain parts to yield more than others. Such lateral deflection increases the bending moment, and consequently increases the tendency to buckle. A compression member is, therefore, in a different condition of equilibrium from one subjected to tension, for in the latter any deviation of the axis from a straight line tends to be diminished by the stress instead of increased.

The oldest theory of columns is due to Euler, and his formula is still the standard for comparison. Euler's theory, however, is based upon the assumptions that the column is perfectly straight, the material perfectly homogeneous, and the load exactly centered at the ends, — assumptions which are never exactly realized. For practical purposes, therefore, it has been found necessary to modify Euler's formula in such a way as to bring it into accord with the results of actual experiments, as explained in the following articles.

82. Euler's theory of long columns. Consider a long column subjected to axial loading, and assume that the column is perfectly straight and homogeneous, and that the load is applied exactly at the centers of gravity of its ends.
Assume also that the ends of the column are free to turn about their
centers of gravity, as would be the case, for example, in a column
with round or pivoted ends.

Now suppose that the column is bent sideways by a lateral force,
and let $P$ be the axial load which is just sufficient to cause the col-
umn to retain this lateral deflection when the lateral force is removed.
Let $OX$ and $OY$ be the axes of $X$ and $Y$ respectively (Fig. 78). Then
if $y$ denotes the deflection of a point $C$ at a distance $x$ from $O$, the
moment at $C$ is $M = Py$. Therefore the differential equation of the
elastic curve assumed by the center line of the column is

$$EI \frac{d^2y}{dx^2} = -Py,$$

which may be written

$$EI \frac{d^2y}{dx^2} + Py = 0.$$

To integrate this differential equation, multiply by $2 \frac{dy}{dx}$. Then

$$2 \frac{d^2y}{dx^2} \frac{dy}{dx} + \frac{2P}{EI} y \frac{dy}{dx} = 0;$$

and integrating each term,

$$\left(\frac{dy}{dx}\right)^2 + \frac{Py^2}{EI} = C_1,$$

where $C_1$ is a constant of integration. This equation can now be written

$$\frac{dy}{\sqrt{\frac{EIC_1}{P} - y^2}} = \sqrt{\frac{P}{EI}} dx.$$

Integrating again,

$$\sin^{-1} \frac{y}{\sqrt{\frac{EIC_1}{P}}} = \sqrt{\frac{P}{EI}} x + C_2,$$

where $C_2$ is also a constant of integration; whence

$$y = \sqrt{\frac{EIC_1}{P}} \sin \left(\sqrt{\frac{P}{EI}} x + C_2\right),$$

* See *Elements of the Differential and Integral Calculus*, pp. 438, 444, by W. A. Granville, Ph.D., with the editorial cooperation of Percey F. Smith, Ph.D. Ginn & Company, 1904.
or, expanding,

\[ y = \sqrt{\frac{EIC_1}{P}} \left[ \sin \left( x \sqrt{\frac{P}{EI}} \right) \cos C_2 + \cos \left( x \sqrt{\frac{P}{EI}} \right) \sin C_2 \right]. \]

Now for convenience let the constants in this integral be denoted by \( A, B, \) and \( C \) respectively; that is to say, let

\[ A = \sqrt{\frac{EIC_1}{P}} \cos C_2; \quad B = \sqrt{\frac{EIC_1}{P}} \sin C_2; \quad C = \sqrt{\frac{P}{EI}}. \]

Then the general integral becomes

\[ y = A \sin Cx + B \cos Cx. \]

At the ends \( O \) and \( X \), where \( x = 0 \) and \( l \), \( y = 0 \). Substituting these values in the above integral,

\[ B = 0, \quad \text{and} \quad A \sin Cl = 0. \]

Since \( A \) and \( B \) cannot both be zero, \( \sin Cl = 0 \); whence

\[ Cl = \sin^{-1}0 = \lambda \pi, \]

where \( \lambda \) is an arbitrary integer. Now let \( \lambda \) take the smallest value possible, namely 1, and substitute for \( C \) its value. Then

\[ l \sqrt{\frac{P}{EI}} = \pi; \]

whence

(48) \[ P = \frac{\pi^2EI}{l^2}, \]

which is Euler's formula for long columns.

Under the load \( P \) given by this formula the column is in neutral equilibrium; that is to say, the load \( P \) is just sufficient to cause it to retain any lateral deflection which may be given to it. For this reason \( P \) is called the critical load. If the load is less than this critical value, the column is in stable equilibrium, and any lateral deflection will disappear when its cause is removed. If the load exceeds this critical value, the column is in unstable equilibrium, and the slightest lateral deflection will rapidly increase until rupture occurs.

83. Columns with one or both ends fixed. The above deduction of Euler's formula is based on the assumption that the ends of the
column are free to turn, and therefore formula (48) applies only to long columns with round or pivoted ends.

If the ends of a column are rigidly fixed against turning, the elastic curve has two points of inflection, say $B$ and $D$. From symmetry, the tangent to the elastic curve at the center $C$ must be parallel to the original position of the axis of the column $AE$, and therefore the portion $AB$ of the elastic curve must be symmetrical with $BC$, and $CD$ with $DE$. Consequently, the points of inflection, $B$ and $D$, occur at one fourth the length of the column from either end. The critical load for a column with fixed ends is, therefore, the same as for a column with free ends of half the length; whence, for fixed ends, Euler's formula becomes

\[ P = \frac{4\pi^2EI}{l^3}. \]  

Columns with flat ends, fixed against lateral movement, are usually regarded as coming under formula (49), the terms "fixed ends" and "flat ends" being used interchangeably.

If one end of the column is fixed and the other end is free to turn, the elastic curve is approximately represented by the line $BCDE$ in Fig. 79. Therefore the critical load in this case is approximately the same as for a column with both ends free, of length $BCD$, that is, of length equal to $\frac{2}{3} BE$ or $\frac{3}{4} l$; whence, for a column with one end fixed and the other free, Euler's formula becomes

\[ P = \frac{9\pi^2EI}{4l^3}, \text{ approximately.} \]

84. Independent proof of formulas for fixed ends.

The results of the preceding article can be established independently as follows.

Suppose both ends of the column fixed against turning by a moment $M_0$ at each support. Then the moment at any point $C$, distant $x$ from 0 (Fig. 80), is $M = -M_0 + Py$, and therefore the equation of the elastic curve is
Proceeding as in Article 82, the general integral of this equation is found to be

\[ y = A \sin \left( x \sqrt{\frac{P}{EI}} \right) + B \cos \left( x \sqrt{\frac{P}{EI}} \right) + \frac{M_0}{P}, \]

in which \( A \) and \( B \) are undetermined constants.* For \( x = 0 \) and \( l \), \( y = 0 \), and \( \frac{dy}{dx} = 0 \). Therefore, by substituting these values in the general integral, the following relations are obtained:

\[ A = 0, \quad B = -\frac{M_0}{P}, \quad B \cos \left( l \sqrt{\frac{P}{EI}} \right) + \frac{M_0}{P} = 0, \]

\[ -B \sqrt{\frac{P}{EI}} \sin \left( l \sqrt{\frac{P}{EI}} \right) = 0. \]

From these conditions,

\[ \cos \left( l \sqrt{\frac{P}{EI}} \right) = 1 \quad \text{and} \quad \sin \left( l \sqrt{\frac{P}{EI}} \right) = 0; \]

whence

\[ \left( l \sqrt{\frac{P}{EI}} \right) = 2 \pi, \]

and consequently

\[ P = \frac{4 \pi^2 EI}{l^2}, \]

which is formula (49) of the preceding article.

Suppose one end of the column is fixed and the other free to turn, and let \( P_h \) denote the horizontal force necessary to keep the free end from lateral movement (Fig. 81). Then the moment at any point \( C \) is \( M = Py - P_h \dot{x} \), and the equation of the elastic curve is

\[ EI \frac{d^2 y}{dx^2} = -Py + P_h \dot{x}. \]

The general integral of this equation is

\[ y = A \sin \left( x \sqrt{\frac{P}{EI}} \right) + B \cos \left( x \sqrt{\frac{P}{EI}} \right) + \frac{P_h \dot{x}}{P}, \]

* * Calculus, p. 440.
in which $A$ and $B$ are undetermined constants.* For $x = 0$ or $l$, $y = 0$; whence

$$B = 0 \quad \text{and} \quad A = -\frac{P_h^l}{P \sin\left(l \sqrt{\frac{P}{EI}}\right)}.$$  

For $x = l$, $\frac{dy}{dx} = 0$; whence

$$P_h \sqrt{\frac{P}{EI}} l \cos\left(l \sqrt{\frac{P}{EI}}\right) - \frac{P_h}{P} = 0.$$  

From the last condition,

$$l \sqrt{\frac{P}{EI}} = \tan\left(l \sqrt{\frac{P}{EI}}\right).$$  

This equation is of the form $u = \tan u$, and from this it is found by trial that

$$l \sqrt{\frac{P}{EI}} = 4.49.$$  

Consequently,

$$P = \frac{20 EI}{l^2} = \frac{2 \pi^2 EI}{l^2},$$  

approximately.

This equation is of the same form as formula (50) of the preceding article, the difference between the numerical constants in the two formulas being due to the approximate nature of the solution given in Article 83.

85. Modification of Euler's formula. It has been found by experiment that Euler's formula applies correctly only to very long columns, and that for short columns or those of medium length it gives a value of $P$ considerably too large.

Very short columns or blocks fail solely by crushing, the tendency to buckle in such cases being practically zero. Therefore, if $p$ denotes the crushing strength of the material and $F$ the area of a cross section, the breaking load for a very short column is $P = pf$.†

* Calculus, p. 440.
† As Euler's formula is based upon the assumption that the column is of sufficient length to buckle sideways, it is evident a priori that it cannot be applied to very short columns in which this tendency is practically zero. Thus, in formula (48), as $l$ approaches zero $P$ approaches infinity, which of course is inadmissible.
For columns of ordinary length, therefore, the load \( P \) must lie somewhere between \( pF \) and the value given by Euler's formula. Consequently, to obtain a general formula which shall apply to columns of any length, it is only necessary to express a continuous relation between \( pF \) and \( \frac{\pi^2EI}{l^2} \). Such a relation is furnished by the equation

\[
P = \frac{pF}{1 + pF\left(\frac{l^2}{\pi^2EI}\right)}
\]

For when \( l = 0 \), \( P = pF \), and when \( l \) becomes very large \( P \) approaches the value \( \frac{\pi^2EI}{l^2} \). Moreover, for intermediate values of \( l \) this formula gives values of \( P \) considerably less than given by Euler's formula, thus agreeing more closely with experiment.

86. Rankine's formula. Although the above modification of Euler's formula is an improvement on the latter, it does not yet agree closely enough with experiment to be entirely satisfactory. The reason for the discrepancy between the results given by this formula and those obtained from actual tests is that the assumptions upon which the formula is based, namely, that the column is perfectly straight, the material perfectly homogeneous, and the load applied exactly at the centers of gravity of the ends, are never actually realized in practice.

To obtain a more accurate formula, two empirical constants will be introduced into equation (51). Thus, for fixed ends, let

\[
P = \frac{gF}{1 + f\left(\frac{l}{t}\right)}
\]

where \( f \) and \( g \) are arbitrary constants to be determined by experiment, and \( t \) is the least radius of gyration of a cross section of the column. This formula has been obtained in different ways by Gordon, Rankine, Navier, and Schwarz.* Among German writers it is known as

*Rankine's formula can be derived independently of Euler's formula either by assuming that the elastic curve assumed by the center line of the column is a sinusoid, or by assuming that the maximum lateral deflection \( D \) at the center of the column is given by the expression \( D = \mu \frac{l^2}{b} \), where \( l \) is the length of the column, \( b \) its least width, and \( \mu \) an empirical constant.
Schwarz’ formula, whereas in English and American text-books it is called Rankine’s formula.

For \( l = 0 \), \( P = gF \), and since short blocks fail by crushing, \( g \) is therefore the ultimate compressive strength of the material.

For different methods of end support Rankine’s formula takes the following forms.

**Flat ends,**

\[
\frac{P}{F} = \frac{g}{1 + f\left(\frac{l}{t}\right)^2}.
\]

**Round ends,**

\[
\frac{P}{F} = \frac{g}{1 + 4f\left(\frac{l}{t}\right)^2}.
\]

**Pin ends,**

\[
\frac{P}{F} = \frac{g}{1 + 2f\left(\frac{l}{t}\right)^2}.
\]

**One end flat and the other round,**

\[
\frac{P}{F} = \frac{g}{1 + 1.78f\left(\frac{l}{t}\right)^2}.
\]

### 87. Values of the empirical constants in Rankine’s formula.

The values of the empirical constants, \( f \) and \( g \), in Rankine’s formula have been experimentally determined by Hodgkinson and Christie with the following results.

- **For hard steel,** \( g = 69,000 \text{ lb./in.}^2 \), \( f = \frac{1}{20,000} \).
- **For mild steel,** \( g = 48,000 \text{ lb./in.}^2 \), \( f = \frac{1}{30,000} \).
- **For wrought iron,** \( g = 36,000 \text{ lb./in.}^2 \), \( f = \frac{1}{36,000} \).
- **For cast iron,** \( g = 80,000 \text{ lb./in.}^2 \), \( f = \frac{1}{6,400} \).
- **For timber,** \( g = 7,200 \text{ lb./in.}^2 \), \( f = \frac{1}{3,000} \).

These constants were determined by experiments upon columns for which \( 20 < \frac{l}{t} < 200 \), and therefore can only be relied upon to
furnish reliable results when the dimensions of the column lie within these limits.

As a factor of safety to be used in applying the formula, Rankine recommended 10 for timber, 4 for iron under dead load, and 5 for iron under moving load.

**Problem 101.** A solid, round, cast-iron column with flat ends is 16 ft. long and 6 in. in diameter. What load may be expected to cause rupture?

**Problem 102.** A square wooden post 12 ft. long is required to support a load of 15 tons. With a factor of safety of 10, what must be the size of the post?

**Problem 103.** Two medium steel Cambria I-beams, No. B 25, weighing 25.25 lb./ft., are joined by lattice work to form a column 25 ft. long. How far apart must the beams be placed, center to center, in order that the column shall be of equal strength to resist buckling in either axial plane?

**Problem 104.** Four medium steel Cambria angles, No. A 101, 3 in. by 5 in. in size, have their 3-in. legs riveted to a ½-in. plate so as to form an I-shaped built column. How wide must the plate be in order that the column shall be of equal strength to resist buckling in either axial plane?

88. **Johnson's parabolic formula.** From the manner in which equation (51) was obtained and afterward modified by the introduction of the empirical constants \( f \) and \( g \), it is clear that Rankine's formula satisfies the requirements for very long or very short columns, while for those of intermediate length it gives the average values of experimental results. A simple formula which fulfills these same requirements has been given by Professor J. B. Johnson, and is called **Johnson's parabolic formula.**

If equation (52) is written

\[
\frac{P}{F} = p = \frac{g}{1 + f \left(\frac{l}{t}\right)^2}
\]

and then \( y \) is written for \( p \), and \( x \) for \( \frac{l}{t} \), Rankine's formula becomes

\[
y = \frac{g}{1 + fx^2}.
\]

For this cubic equation Johnson substituted the parabola

\[
y = \delta - \epsilon x^2,
\]

in which \( x \) and \( y \) have the same meaning as above, and \( \delta \) and \( \epsilon \) are empirical constants. The constants \( \delta \) and \( \epsilon \) are then so chosen that
the vertex of this parabola is at the elastic limit of the material on the axis of loads (or Y-axis), and the parabola is also tangent to Euler's curve. In this way the formula is made to satisfy the theoretical requirements for very long or very short columns, and for those of intermediate length it is found to agree closely with experiment.

For different materials and methods of end support Johnson's parabolic formulas, obtained as above, are as follows:

<table>

</table>

The limit for use in each case is the value of $x \left(= \frac{l}{t}\right)$ at the point where Johnson's parabola becomes tangent to Euler's curve. For greater values of $\frac{l}{t}$ Euler's formula should therefore be used.

* In the formulas for timber $t'$ is the least lateral dimension of the column.
A graphical representation of the relation between Euler's formula, Rankine's formula, J. B. Johnson's parabolic formula, and T. H. Johnson's straight-line formula (considered in the next article) is given in Fig. 82, for the case of a wrought-iron column with pin ends.*

Problem 105. A hollow wrought-iron column with flat ends is 20 ft. long, 7 in. internal diameter, and 10 in. external diameter. Calculate its ultimate strength by Rankine's and Johnson's formulas, and compare the results.

Problem 106. Compute the ultimate strength of the built column in Problem 103 by Rankine's and Johnson's formulas, and compare the results.

89. Johnson's straight-line formula. By means of an exhaustive study of experimental data on columns, Mr. Thomas H. Johnson has shown that for columns of moderate length a straight line can be made to fit the plotted results of column tests as exactly as a curve. He has therefore proposed the formula

\[
P = \nu - \sigma \frac{l}{t},
\]

or, in the notation of the preceding article,

\[
y = \nu - \sigma x,
\]
in which \(\nu\) and \(\sigma\) are empirical constants, this being the equation of a straight line tangent to Euler's curve. This formula has the merit of great simplicity, the only objection to it being that for short columns it gives a value of \(P\) in excess of the actual breaking load. The relation of this formula to those which precede is shown in Fig. 82.

The constants \(\nu\) and \(\sigma\) in formula (53) are connected by the relation

\[
\sigma = \frac{\nu}{3} \sqrt{\frac{4}{3} \frac{v}{n \pi^2 E}},
\]

where for fixed ends \(n = 1\), for free ends \(n = 4\), and for one end fixed and the other free \(n = 1.78\).

The table on page 110 gives the special forms assumed by Johnson's straight-line formula for various materials and methods of end support.*

The limit for use in this case is the value of \(x \left(= \frac{l}{t}\right)\) for the point at which Johnson's straight line becomes tangent to Euler's curve.

**Problem 107.** Compute the ultimate strength of the column in Problem 104 by Rankine's and Johnson's straight-line formulas, and compare the results.

**Problem 108.** A column 18 ft. long is formed by joining the legs of two Carnegie steel channels, No. C3, weighing 30 lb./ft., by two plates each 10 in. wide and \(\frac{3}{4}\) in. thick, as shown in Fig. 83. Find the safe load for this column by Johnson's straight-line formula, using a factor of safety of 4.

**Problem 109.** A wrought-iron pipe 10 ft. long, and of internal and external diameter 3 in. and 4 in. respectively, bears a load of 7 tons. What is the factor of safety?

90. Cooper's modification of Johnson's straight-line formula. In his standard bridge specifications, Theodore Cooper has adopted Johnson's straight-line formulas, modifying them by the introduction of a factor of safety. Thus, for medium steel, Cooper specifies that the following formulas shall be used in calculating the safe load.

For chords

\[
\begin{align*}
\frac{P}{F} &= 8,000 - 30 \frac{l}{l} \text{ for live load stresses,} \\
\frac{P}{F} &= 16,000 - 60 \frac{l}{l} \text{ for dead load stresses.}
\end{align*}
\]
For posts
\[
\frac{P}{F} = 7,000 - 40 \frac{l}{t} \quad \text{for live load stresses},
\]
\[
\frac{P}{F} = 14,000 - 80 \frac{l}{t} \quad \text{for dead load stresses},
\]
\[
\frac{P}{F} = 10,000 - 60 \frac{l}{t} \quad \text{for wind stresses}.
\]

For lateral struts
\[
\frac{P}{F} = 9,000 - 50 \frac{l}{t} \quad \text{for initial stresses}.
\]

By initial stress in the last formula is meant the stress due to the adjustment of the bridge members during construction.

**Problem 110.** What must be the size of a square steel strut 8 ft. long, to transmit a load of 5 tons with safety?

**Problem 111.** Design a column 16 ft. long to be formed of two channels joined by two plates and to support a load of 20 tons with safety.

**Problem 112.** Using Cooper's formula for live load, design the inclined end post of a bridge which is 25 ft. long and bears a load of 30 tons, the end post to be composed of four angles, a top plate, and two side plates.

**91. Beams of considerable depth.** When narrow beams of considerable depth are subjected to compression, as, for example, in a deck plate girder bridge, the strain is similar to that in a column. For a narrow, deep beam the inertia ellipse is greatly elongated, and consequently the radius of gyration relative to a line forming a small angle with the horizontal is considerably less than the semi-major axis of the ellipse. Therefore, if the beam is thrown slightly out of the vertical by the unequal settling of its supports, or by any other cause, such inclination results in a notable decrease in its resistance. Since it is impossible to make allowances for such accidental reductions of strength, beams of great depth or very thin web should be avoided.
CHAPTER VI

TORSION

92. Circular shafts. When a uniform circular shaft, such as shown in Fig. 84, is twisted by the application of moments of opposite signs to its ends, every straight line $AB$ parallel to its axis is deformed into part of a helix, or screw thread, $AC$. The strain in this case is one of pure shear and is called torsion, as mentioned in Article 37. The angle $\phi$ is called the angle of shear (compare Article 33), and is proportional to the radius $BD$ of the shaft. The angle $\theta$ is called the angle of twist, and is proportional to the length $AB$ of the shaft.

![Fig. 84](image1)

![Fig. 85](image2)

93. Maximum stress in circular shafts. Consider a section of length $dx$ cut from a circular shaft by planes perpendicular to its axis (Fig. 85). Let $d\theta$ denote the angle of twist for this section. Then, since the angle of twist is proportional to the length of the shaft, $d\theta : \theta = dx : l$; whence

$$d\theta = \theta \frac{dx}{l}.$$  

Also, if $\phi$ and $d\theta$ are expressed in circular measure,

$$BC = \phi \cdot AB = \phi dx,$$

and

$$BC = d\theta \cdot BD = r d\theta.$$  

Therefore

$$\phi = \frac{r d\theta}{dx} = r \frac{\theta}{l}.$$
From Hooke's law (Article 33), \( \frac{q}{\phi} = G \). Hence

(54) \[ q = G\phi = \frac{Gr\theta}{l}. \]

Therefore \( q \) is proportional to \( r \); that is to say, the unit shear is proportional to its distance from the center, being zero at the center and attaining its maximum value at the circumference.

If \( q' \) denotes the intensity of the shear at the circumference and \( a \) denotes the radius of the shaft, then the shear \( q \) at a distance \( r \) from the center is given by the formula

\[ q = \frac{q'r}{a}. \]

Let \( M \) denote the external twisting moment. Then, since \( M \) must be equal to the internal moment of resistance,

\[ M = \int qrdF = \frac{q'}{a} \int r^2dF = \frac{q'Ip}{a}, \]

where \( Ip \) is the polar moment of inertia of the section.

For a solid circular shaft \( Ip = \pi a^4 \), and consequently

(55) \[ q' = \frac{Ma}{Ip} = \frac{2M}{\pi a^3}. \]

For a hollow circular shaft of external radius \( a \) and internal radius \( b \), \( Ip = \frac{\pi (a^4 - b^4)}{2} \), and hence

(56) \[ q' = \frac{2Ma}{\pi (a^4 - b^4)}. \]

94. Angle of twist in circular shafts. From equation (54),

\[ \theta = \frac{ql}{Gr} = \frac{q'l}{Ga}. \]

Therefore, for a solid circular shaft, from equation (55),

(57) \[ \theta = \frac{2Ml}{\pi a^3 G}; \]
and for a hollow circular shaft, from equation (56),

\[ \theta = \frac{2 Ml}{\pi G(a^4 - b^4)}. \]

If \( M \) is known and \( \theta \) can be measured, equations (57) and (58) can be used for determining \( G \). If \( G \) is known and \( \theta \) measured, these equations can be used for finding \( M \); in this way the horse power which a rotating circular shaft is transmitting can be determined.

**Problem 113.** A steel wire 20 in. long and .182 in. in diameter is twisted by a moment of 20 in. lb. The angle of twist is then measured and found to be \( \theta = 18^\circ 31' \). What is the value of \( G \) determined from this experiment?

**Problem 114.** If the angle of twist for the wire in Problem 113 is \( \theta = 40^\circ \), how great is the torsional moment acting on the wire?

95. **Power transmitted by circular shafts.** Let \( H \) be the number of horse power transmitted by the shaft, and \( n \) the number of revolutions it makes per minute. Then, if \( q \) is the force acting on a particle at a distance \( r \) from the center, the moment of this force is \( qr \), and consequently the total moment transmitted by the shaft is \( M = \int qr \). Also, the distance traveled by \( q \) in one minute is \( 2 \pi r n \), and therefore the total work transmitted by the shaft is

\[ W = \int 2 \pi r n q. \]

Since 1 horse power = 33,000 ft. lb./min. = 396,000 in. lb./min., the total work done by the shaft is

\[ W = 396,000 H \text{ in. lb./min.} \]

Therefore

\[ 2 \pi n \int rq = W = 396,000 H, \]

or

\[ 2 \pi n M = 396,000 H; \]

whence

\[ M = \frac{396,000 H}{2 \pi n} = 63,030 \frac{H}{n} \text{ in. lb.} \]

Therefore, if it is required to find the diameter \( d \) of a solid circular shaft which shall transmit a given horse power \( H \) with safety, then, from equation (55),

\[ q' = \frac{2 M}{\pi a^4} = \frac{16 M}{\pi d^4} = \frac{321,000 H}{nd^4}; \]
whence

\[ d = 68.5 \sqrt[3]{\frac{H}{nq'}}. \]  

As safe values for the maximum unit shear \( q' \) Ewing recommends 9000 lb./in.\(^2\) for wrought iron, 13,500 lb./in.\(^2\) for steel, and 4500 lb./in.\(^2\) for cast iron.* Inserting these values of \( q' \) in formula (59), it becomes

\[ d = \mu \sqrt[3]{\frac{H}{n}}, \]  

where for steel \( \mu = 2.88 \), for wrought iron \( \mu = 3.29 \), and for cast iron \( \mu = 4.15 \).

Formulas (59) and (60) were deduced under the assumption that the action of the external moment was uniform. In many cases, however, this assumption is not verified. For example, if a shaft is driven by one or more cranks, the moment varies periodically. Under such conditions the diameter of the shaft should be somewhat larger than the value of \( d \) given by equation (60).

**Problem 115.** Find the diameter of a solid wrought-iron circular shaft which is required to transmit 150 H.P. at a speed of 60 revolutions per minute.

**Problem 116.** A steel shaft is required to transmit 300 H.P. at a speed of 200 revolutions per minute, the maximum moment being 40 per cent greater than the average. Find the diameter of the shaft.

**Problem 117.** Under the same conditions as in Problem 116, find the inside diameter of a hollow circular shaft whose outside diameter is 6 in. Also compare the amount of metal in the solid and hollow shafts.

**Problem 118.** How many H.P. can a hollow circular steel shaft of 15 in. external diameter and 11 in. internal diameter transmit at a speed of 50 revolutions per minute, if the maximum allowable unit stress is not to exceed 12,000 lb./in.\(^2\)?

**96. Combined bending and torsion.** When a shaft transmits power by means of a crank or pulley, it is subjected to combined bending and torsion. For example, if a force \( P \) acts at a point \( A \) in the crank pin shown in Fig. 86, the bending moment at any point \( C \) of

the shaft is \( M_1 = Pd^2 \), and the torsional moment at \( C \) is \( M_2 = Pd_1 \).

Therefore, if \( a \) is the radius of the shaft at \( C \), the normal stress on the extreme fiber due to bending is

\[
p = \frac{4 M_1}{\pi a^3},
\]

and the shearing stress on the extreme fiber due to torsion is

\[
q = \frac{2 M_2}{\pi a^3}.
\]

There is also a shearing stress of amount \( P \) distributed over the cross section through \( C \), but since it is zero at the outer fiber it does not enter into this calculation.

From Article 26, the values of the principal stresses are

\[
p'_{\text{max}} = \frac{p}{2} \pm \frac{1}{2} \sqrt{4 q^2 + p^2},
\]

and from Article 28, the maximum or minimum shear is

\[
q'_{\text{max}} = \pm \frac{1}{2} \sqrt{4 q^2 + p^2}.
\]

Inserting in these expressions the values of \( p \) and \( q \) obtained above, the principal stresses and the maximum or minimum shear are, in the present case,

\[
p'_{\text{max}} = \frac{2}{\pi a^3} \left( M_1 \pm \sqrt{M_1^2 + M_2^2} \right),
\]

\[
q'_{\text{max}} = \pm \frac{2}{\pi a^3} \sqrt{M_1^2 + M_2^2}.
\]

The equivalent stress may also be found. Thus, from equation (15), Article 36, its value is

\[
p_e = \frac{m - 1}{2m} p \pm \frac{m + 1}{2m} \sqrt{4 q^2 + p^2}.
\]

Inserting the values of \( p \) and \( q \) from the above, this becomes

\[
p_e = \frac{2}{\pi a^3} \left( \frac{M_1 (m - 1)}{m} \pm \frac{m + 1}{m} \sqrt{M_1^2 + M_2^2} \right).
\]

If the value of \( m \) is assumed to be \( 3 \frac{1}{3} \), then

\[
p_e = \frac{2}{\pi a^3} \left( 7 \ M_1 \pm 1.3 \ \sqrt{M_1^2 + M_2^2} \right).
\]
Problem 119. A steel shaft 5 in. in diameter is driven by a crank of 12-in. throw, the maximum thrust on the crank being 10 tons. If the outer edge of the shaft bearing is 11 in. from the center of the crank pin, what is the equivalent stress in the shaft at this point?

Problem 120. A steel shaft 10 ft. long between bearings and 4 in. in diameter carries a pulley 14 in. in diameter at its center. If the tension in the belt on this pulley is 250 lb., and the shaft makes 80 revolutions per minute, what is the maximum stress in the shaft and how many H.P. is it transmitting?

*97. Resilience of circular shafts.* In Article 73 the resilience of a body was defined as the internal work of deformation. For a solid circular shaft this internal work is

\[ W = \frac{1}{2} M \theta , \]

where \( M \) is the external twisting moment and \( \theta \) is the angle of twist.

From equation (54), \( \theta = \frac{q l}{G r} = \frac{q l}{G a} \), and from equation (55), \( M = \frac{\pi a^3 q l}{2} \).

Therefore the total resilience of the shaft is

\[ W = \frac{1}{2} M \theta = \frac{\pi a^2 q^2 l}{4 G} , \]

and consequently the mean resilience per unit of volume is

\[ W_1 = \frac{W}{V} = \frac{q l^2}{4 G} . \]

98. Non-circular shafts. The above investigation of the distribution and intensity of torsional stress applies only to shafts of circular section. For other forms of cross section the results are entirely different, each form having its own peculiar distribution of stress.

For any form of cross section whatever, the stress at the boundary must be tangential. For if the stress is not tangential, it can be resolved into two components, one tangential and the other normal to the boundary; and in Article 23 it was shown that such a normal component would necessitate forces parallel to the axis of the shaft, which are excluded by hypothesis.

Since the stress at the boundary must be tangential, the circular section is the only one for which the stress is perpendicular to a radius vector. Therefore the circular section is the only one to which the above development applies, and consequently is the only form of

*For a brief course the remainder of this chapter may be omitted.*
cross section for which Bernoulli’s assumption holds true. That is to say, the circular section is the only form of cross section which remains plane under a torsional strain.

The subject of the distribution of stress in non-circular shafts has been investigated by St. Venant, and the results of his investigations are summarized below (Articles 99–102 inclusive).

99. Elliptical shaft. For a shaft the cross section of which is an ellipse of semi-axes a and b, the maximum stress occurs at the ends of the minor axis, instead of at the ends of the major axis, as might be expected. The unit stress at the ends of the minor axis is given by the formula

\[ q_{\text{max}} = \frac{2M}{\pi ab^3} \]

and the angle of twist per unit of length is

\[ \theta_1 = \frac{M(a^2 + b^3)}{\pi a^3 b^3 G} \]

The total angle of twist for an elliptical shaft of length l is therefore

\[ \theta = \theta_1 l = \frac{M(a^2 + b^3)l}{\pi a^3 b^3 G} \]

Problem 121. The semi-axes of the cross section of an elliptical shaft are 3 in. and 5 in. respectively. What is the diameter of a circular shaft of equal strength?

100. Rectangular and square shafts. For a shaft of rectangular cross section the maximum stress occurs at the centers of the longer sides, its value at these points being

\[ q_{\text{max}} = \frac{6M}{hb \sqrt{h^2 + b^2}} \left(0.68 + 0.45 \frac{h}{b}\right) \]

in which h is the longer and b the shorter side of the rectangle. The angle of twist per unit of length is, in this case,

\[ \theta_1 = 3.57 \frac{M(h^2 + b^2)}{Gb h b^3} \]

For a square shaft of side b these formulas become

\[ q_{\text{max}} = 4.8 \frac{M}{b^3}, \]

and

\[ \theta_1 = 7.14 \frac{M}{Gb^3}. \]
The value of \( q \) for a square shaft found from this equation is about 15 per cent greater than if the formula \( q = \frac{Mr}{I_p} \) was used, and the torsional rigidity is about .88 of the torsional rigidity of a circular shaft of equal sectional area.

**Problem 122.** An oak beam 6 in. square projects 4 ft. from a wall and is acted upon at the free end by a twisting moment of 25,000 ft. lb. How great is the angle of twist?

**101. Triangular shafts.** For a shaft whose cross section is an equilateral triangle of side \( c \),

\[
q_{\text{max}} = 20 \frac{M}{c^3},
\]

and the angle of twist per unit of length is

\[
\theta_1 = \frac{M}{.6 \, G I_p}.
\]

The torsional rigidity of a triangular shaft is therefore .73 of the torsional rigidity of a circular shaft of equal sectional area.

**102. Angle of twist for shafts in general.** The formula for the angle of twist per unit of length for circular and elliptical shafts can be written

\[
\theta_1 = 4 \frac{\pi^2 M}{G} \cdot \frac{I_p}{E^4},
\]

in which \( I_p \) is the polar moment of inertia of a cross section about its center, and \( E \) is the area of the cross section. This formula is rigorously true for circular and elliptical shafts, and St. Venant has shown that it is approximately true whatever the form of cross section.

**Problem 123.** Compare the angle of twist given by St. Venant's general formula with the values given by the special formulas in Articles 99, 100, and 101.

**Problem 124.** Find the angle of twist in Problem 116.

**Problem 125.** Find the angle of twist in Problem 117, and compare it with the angle of twist for the solid shaft in Problem 124.

**103. Helical springs.** The simplest form of a helical, or spiral, spring is formed by wrapping a wire upon a circular cylinder, the form of such a spring being that of a screw thread. Let \( r \) be the radius of the coil and \( a \) the radius of the wire, and let the spring be either compressed or extended by
two forces $P$ acting in the direction of the axis of the cylinder (Fig. 87). Then the bending moment at any point of the spring is $M = Pr$. If the radius $r$ of the coil is large in comparison with the diameter of the wire, and if the spring is closely wound, the plane of the external moment $M$ is very nearly perpendicular to the axis of the helix, and consequently the bending strain can be assumed to be zero in comparison with the torsional strain. Under this assumption the maximum stress is found, from equation (55), to be

$$q' = q_{\text{max}} = \frac{2M}{\pi a^3} = \frac{2Pr}{\pi a^3}.$$

Similarly, the maximum stress in a spring of square or rectangular cross section can be found by substituting $M = Pr$ in equations (61) and (62).

To find the amount by which the spring is extended or compressed, let $d\theta$ be the angle of twist for an element of the helix of length $dl$. Then (Fig. 88), if $AB$ is the axis of the spring, a point $M$ in this axis in the same horizontal plane with the element $dl$ is displaced vertically an amount $MN = rd\theta$ in the direction of the axis. Therefore the total axial compression or extension $D$ of the spring is the sum of all the infinitesimal displacements $rd\theta$ for every element $dl$; whence

$$D = \int rd\theta.$$

From equation (57), $\theta = \frac{2Ml}{\pi a^4 G} = \frac{2Pr}{\pi a^4 G}$.

Therefore $d\theta = \frac{2Pr}{\pi a^4 G} dl$, and consequently

$$D = \int_0^l \frac{2Pr^2}{\pi a^4 G} dl = \frac{2Pr^2}{\pi a^4 G} \int_0^l dl = \frac{2Pr^2 l}{\pi a^4 G},$$

in which $l$ is the length of the helix.

If $n$ denotes the number of turns of the helix, then, under the above assumption that the slope of the helix is small, $l = 2\pi rn$ approximately, and hence
The resilience \( W \) of the spring is equal to one half the product of the force \( P \) multiplied by the axial extension or compression of the spring. Hence

\[
W = \frac{1}{2} PD = \frac{P^2 r^2 l}{\pi a^4 G}.
\]

If the obliquity of the helix is so large that it cannot be neglected in analyzing the stress, the external moment \( M \) acting at any point of the helix must be resolved into two components,—a torsional moment lying in a plane perpendicular to the axis of the helix, and a bending moment lying in a plane through the axis of the helix. Under the action of these two moments it can be shown that there will be a horizontal as well as a vertical angular displacement; that is, if the spring is pulled, it will not only undergo axial extension but will also coil up or uncoil. The result is not of sufficient practical importance to warrant a demonstration of it being given here. It may be mentioned, however, that if the wire is of circular cross section, a pull will make the helix coil more closely, whereas if a section of the wire is a deep and narrow rectangle, a pull will make the helix uncoil.

**Problem 126.** A helical spring is composed of 20 turns of steel wire .258 in. in diameter, the diameter of the coil being 3 in. If the spring is compressed by a force of 50 lb., what is the maximum stress in the spring, its axial compression, and its resilience?
CHAPTER VII

SPHERES AND CYLINDERS UNDER UNIFORM PRESSURE

104. Hoop stress. When a hollow sphere or cylinder is subjected to uniform pressure, as in the case of steam boilers, standpipes, gas, water, and steam pipes, fire tubes, etc., the effect of the radial pressure is to produce stress in a circumferential direction, called hoop stress. In the case of a cylinder closed at the ends, the pressure on the ends produces longitudinal stress in the side walls in addition to the hoop stress.

If the thickness of a cylinder or sphere is small as compared with its diameter, it is called a shell. In analyzing the stress in a thin shell subjected to uniform pressure, such as that due to water, steam, or gas, it may be assumed that the hoop stress is distributed uniformly over any cross section of the shell. This assumption will be made in what follows.

105. Hoop tension in hollow sphere. Consider a spherical shell subjected to uniform internal pressure, and suppose that the shell is cut into hemispheres by a diametral plane (Fig. 89). Then, if \( w \) denotes the pressure per unit of area within the shell, the resultant force acting on either hemisphere is \( P = \pi r^2 w \), where \( r \) is the radius of the sphere. If \( p \) denotes the unit tensile stress on the circular cross section of the shell, the total stress on this cross section is \( 2 \pi rhp \), approximately, where \( h \) is the thickness of the shell. Consequently, \( \pi r^2 w = 2 \pi rhp \); whence

\[
p = \frac{wr}{2h},
\]

which gives the hoop tension in terms of the radial pressure.

From symmetry, the stress is the same on any diametral cross section. Therefore the equivalent stress at any point of the shell is
If the value of $m$ is assumed to be $3\frac{1}{3}$, this expression for $p_e$ becomes

$$ p_e = \frac{m - 1}{m} p = \frac{m - 1}{m} \cdot \frac{wr}{2h}. $$

Problem 127. How great is the stress in a copper sphere 2 ft. in diameter and .25 of an inch thick, under an internal pressure of 175 lb./in.$^2$?

106. **Hoop tension in hollow circular cylinder.** In the case of a cylindrical shell, its ends hold the cylindrical part together in such a way as to relieve the hoop tension at either extremity. Suppose, then, that the portion of the cylinder considered is so far removed from either end that the influence of the end constraint can be assumed to be zero.

Suppose the cylinder cut in two by a plane through its axis, and consider a section cut out of either half cylinder by two planes perpendicular to the axis, at a distance apart equal to $c$ (Fig. 90). Then the resultant internal pressure $P$ on the strip under consideration is $P = 2crw$, and the resultant hoop tension is $2chp$, where the letters have the same meaning as in the preceding article. Consequently, $2crw = 2chp$; whence

$$ p = \frac{rw}{h}. $$

If the longitudinal stress is zero, $p_e = p$.

This result is applicable to shells under both inner and outer pressure, if $P$ is taken to be the excess of the internal over the external pressure.

Problem 128. A cast-iron water pipe is 24 in. in diameter and 2 in. thick. What is the greatest internal pressure which it can withstand?

107. **Longitudinal stress in hollow circular cylinder.** If the ends of a cylinder are fastened to the cylindrical part, the internal pressure against the ends produces longitudinal stresses in the side walls. In this case the cylindrical part is subjected both to hoop tension and to longitudinal tension.
To find the amount of the longitudinal tension, consider a cross section of the cylinder near its center, where the influence of the end restraints can be assumed to be zero (Fig. 91). Then the resultant pressure on either end is \( P = \pi r^2 w \), and the resultant longitudinal stress on the cross section is \( 2 \pi rh p \). Therefore
\[
\pi r^2 w = 2 \pi rh p; \quad \text{whence} \quad p = \frac{rw}{2h}.
\]
This is the same formula as for the sphere, which was to be expected, since the cross section is the same in both cases.

If \( p_l \) denotes the longitudinal stress and \( p_h \) the hoop tension, then
\[
p_l = \frac{rw}{2h}, \quad p_h = \frac{rw}{h}; \quad \text{and, consequently, the equivalent stress} \quad p_e \text{ is}
\]
\[
p_e = p_h - \frac{1}{m} p_l = \frac{2m - 1}{2m} \frac{wr}{h}.
\]
If \( m = 3\frac{1}{3} \), this becomes
\[
(65) \quad p_e = .85 \frac{wr}{h}.
\]

Formula (65) is the one to be used in finding the tensile stress in a thin cylinder subjected to uniform internal pressure, in which the ends are held together by the body of the cylinder and not by independent stays or fixed supports.

**Problem 129.** An elevated water tank is cylindrical in form with a hemispherical bottom (Fig. 92). The diameter of the tank is 20 ft. and its height 52 ft., exclusive of the bottom. If the tank is to be built of wrought iron and the factor of safety is taken to be 6, what should be the thickness of the bottom plates, and also of those in the body of the tank near its bottom?

**Note.** Formulas (63) and (65) give the required thickness of the plates, provided the tank is without joints. The bearing power of the rivets at the joints, however, is, in general, the consideration which determines the thickness of the plates.
**Problem 130.** A marine boiler shell is 16 ft. long, 8 ft. in diameter, and 1 in. thick. What is the stress in the shell for a working gauge pressure of 160 lb./in.²?

**Problem 131.** The air chamber of a pump is made of cast iron of the form shown in Fig. 93. If the diameter of the air chamber is 10 in. and its height 24 in., how thick must the walls of the air chamber be made to stand a pressure of 500 lb./in.² with a factor of safety of 4?

*108. Differential equation of elastic curve for circular cylinder.*

A cylindrical shell subjected to internal pressure is in a condition of stable equilibrium, for the internal pressure tends to preserve the cylindrical form of the shell, or to restore it to this form if, by any cause, the cylinder is flattened or otherwise deformed. A cylindrical shell which is subjected to external pressure, however, is in a condition of unstable equilibrium, for any deviation from a cylindrical form tends to be increased rather than diminished by the stress. In this respect thin hollow cylinders under external pressure are in a state of strain similar to that in a column, and the method of finding the critical pressure just preceding collapse is similar to that for finding the critical load for a column, as explained in the derivation of Euler's formula.

Consider a thin hollow cylinder which is subjected to a uniform external pressure of amount \( w \) per unit of area, and suppose that in some way the cylinder has been compressed in one direction so that it assumes the flattened form shown in Fig. 94. The first step in the solution of the problem is to find the differential equation of the elastic curve in curvilinear coördinates, or, in other words, the differential equation of the elastic curve of the flattened cylinder referred to its original circular form.

In polar coördinates let \( O \) be the origin and \( OA \) the initial line. Also, let \( a \) denote the radius of the circular cylinder, and \( r \) the radius vector of the flattened or elliptical form. Now suppose that the circular wall of the cylinder is considered as a piece which was originally straight and has been made to assume a circular form by a

---

*For a brief course the remainder of this chapter may be omitted.*
bending moment $M'$. Then, if $\rho$ denotes the radius of curvature, from Article 66,

$$\frac{1}{\rho} = \frac{M'}{EI}.$$  

Again, suppose that this circular cylinder is made to assume the flattened form as the result of an additional bending moment $M$, and let $\rho'$ denote the corresponding radius of curvature. Then

$$\frac{1}{\rho'} = \frac{M' + M}{EI}.$$  

Consequently,

$$(66) \quad \frac{1}{\rho'} - \frac{1}{\rho} = \frac{M}{EI}.$$  

From the differential calculus,*

$$\rho' = \frac{\sqrt{r^2 + \left(\frac{dr}{d\alpha}\right)^2}}{r^2 + 2\left(\frac{dr}{d\alpha}\right)^2 - r\frac{d^2r}{d\alpha^2}}.$$  

If the deformation is small, $\frac{dr}{d\alpha}$ is infinitesimal, and $r$ differs infinitesimally from $a$. Therefore, neglecting infinitesimals of an order higher than the second, the expression for $\rho'$ becomes

$$\rho' = \frac{a^2}{a^2 - a\frac{d^2r}{d\alpha^2}} = \frac{a^2}{a - \frac{d^2r}{d\alpha^2}}.$$  

and, consequently,

$$\frac{1}{\rho'} = \frac{1}{a} - \frac{1}{a^2} \frac{d^2r}{d\alpha^2}.$$  

Since $\rho = a$, $\frac{1}{\rho} = \frac{1}{a}$, and therefore

$$(67) \quad \frac{1}{\rho'} - \frac{1}{\rho} = \frac{1}{a} \frac{d^2r}{d\alpha^2}.$$  

Comparing equations (66) and (67),

$$(68) \quad \frac{1}{a^2} \frac{d^2r}{d\alpha^2} = \pm \frac{M}{EI}.$$  

* *Calculus*, p. 163.

† The sign $\pm$ is used because the calculus expression for $\rho'$ contains a square root in the numerator.
Now let $u$ denote the distance between the circle and the ellipse measured radially. Then

$$r = u \pm a,$$

or, if $u$ is assumed to be positive when it lies outside the circle and negative when it lies inside,

$$r = u + a.$$

Differentiating both sides of this equation with respect to $\alpha$,

$$\frac{dr}{d\alpha} = \frac{du}{d\alpha}, \quad \frac{d^2r}{d\alpha^2} = \frac{d^2u}{d\alpha^2}.$$

Also, if $dl$ is the length of an infinitesimal arc of the circle, $a d\alpha = dl$. Substituting these values in equation (68), it becomes

$$(69) \quad E I \frac{d^2u}{dl^2} = \pm M,$$

which is the required differential equation of the elastic curve in the curvilinear co-ordinates $l$ and $u$.

109. Crushing strength of hollow circular cylinder. As a continuation of the preceding article, let it be required to find the external pressure which is just sufficient to cause the cylinder to retain its flattened form, or, in other words, the critical external pressure just preceding collapse.

In Fig. 95 let $OA$ and $OB$ be axes of symmetry; then it is sufficient to consider merely the quadrant $AOB$. Let $e$ denote the length of the chord $AC$, and let $w$ be the unit external pressure. Then for a section of the cylinder of unit length the external pressure $P$ on the curved strip $AC$ is

$$P = wc.$$

Now let $M_o$ denote the bending moment at the point $A$. The tangential force at this point is equal to the resultant pressure on $OA$, or $wb$. Consequently the bending moment $M$ at the point $C$ is

$$M = M_o + wb \cdot AD - wc \cdot \frac{c}{2} = M_o + w \left( b \cdot AD - \frac{c^2}{2} \right).$$
In the triangle $OAC$,
\[ OC^2 = AC^2 + AO^2 - 2 AO \cdot AD, \]
or
\[ r^2 = c^2 + b^2 - 2 b \cdot AD, \]
from which
\[ b \cdot AD - \frac{c^2}{2} = \frac{b^2 - r^2}{2}. \]
Hence
\[ M = M_0 + \frac{w(b^2 - r^2)}{2}. \]
Since \( r = u + a \) and \( a = b - u_0 \),
\[ M = M_0 + \frac{w}{2} (a^2 + 2 awu + u_0^2 - a^2 - 2 au - u^3) \]
\[ = M_0 + \frac{w}{2} (u_0 - u) (u_0 + u + 2 a). \]
Since \( u \) and \( u_0 \) are both infinitesimal, \( u_0 + u \) (or the difference between the absolute values of \( u \) and \( u_0 \)) is negligible in comparison with \( 2 a \). Therefore
\[ M = M_0 - wa (u - u_0), \]
and, consequently, the differential equation of the elastic curve becomes
\[ EI \frac{d^2u}{dl^2} = M_0 - wa (u - u_0). \]
The general integral of this differential equation is found to be
\[ (70) \quad u = u_0 + \frac{M_0}{wa} + C_1 \sin \sqrt{\frac{wa}{EI}} l + C_2 \cos \sqrt{\frac{wa}{EI}} l, \]
in which \( C_1 \) and \( C_2 \) are the undetermined constants of integration.†
This may be verified by substituting the integral in the above differential equation.
To determine \( C_1 \) and \( C_2 \) it is only necessary to make use of the terminal conditions at \( A \) and \( B \). At the point \( A, l = 0, \frac{du}{dl} = 0, \) and \( u = u_0 \). Substituting these values in equation (70) and its first derivative, it is found that
\[ C_1 = 0 \quad \text{and} \quad C_2 = - \frac{M_0}{wa}. \]

* Throughout this discussion it should be borne in mind that \( u_0 \) is a negative quantity.
† See Johnson, Treatise on Ordinary and Partial Differential Equations, 3d ed., pp. 85-86; also Calculus, p. 440.
Hence the integral becomes

\[ u = \frac{M_0}{wa} + u_0 - \frac{M_0}{wa} \cos \sqrt{\frac{wa}{EI}} l, \]

or

\[ (71) \quad u = \frac{M_0}{wa} \left( 1 - \cos \sqrt{\frac{wa}{EI}} l \right) + u_0 \]

At the upper end of the quadrant \( B \) the conditions are \( l = \frac{\pi a}{2} \) and \( \frac{du}{dl} = 0 \). Substituting these values in the first differential coefficient obtained from equation (71), namely,

\[ \frac{du}{dl} = \frac{M_0}{wa} \sqrt{\frac{wa}{EI}} \sin \sqrt{\frac{wa}{EI}} l, \]

we have

\[ \sin \left( \sqrt{\frac{wa}{EI}} \cdot \frac{\pi a}{2} \right) = 0; \]

whence

\[ \sqrt{\frac{wa}{EI}} \cdot \frac{\pi a}{2} = \lambda \pi, \]

where \( \lambda \) is an arbitrary integer. Choosing the smallest value of \( \lambda \), namely 1, this condition becomes

\[ \sqrt{\frac{wa}{EI}} \cdot \frac{a}{2} = 1; \]

whence

\[ (72) \quad w = \frac{4 EI}{a^3}. \]

If the thickness of the tube is denoted by \( h \), then, for a section of unit length, \( I = \frac{h^3}{12} \), and formula (72) becomes

\[ (73) \quad w = \frac{E}{3} \left( \frac{h}{a} \right)^3. \]

Formula (73) gives the critical pressure just preceding collapse; that is to say, it gives the maximum external pressure \( w \) per unit of area which a cylindrical tube of thickness \( h \) can stand without crushing.

**Problem 132.** What is the maximum external pressure which a cast-iron pipe 18 in. in diameter and \( \frac{1}{2} \) in. thick can stand without crushing?
**Problem 133.** In a fire-tube boiler the tubes are of drawn steel, 2 in. internal diameter and $\frac{1}{4}$ in. thick. What is the factor of safety for a working gauge pressure of 200 lb./in.$^2$?

110. **Thick cylinders; Lamé's formulas.** Consider a thick circular cylinder of external radius $a$ and internal radius $b$, which is subjected to the action of either internal or external uniform pressure, or to both. Suppose a section is cut out of the cylinder by two planes perpendicular to the axis at a unit's distance apart, and consider a small sector $ABCD$ of angle $\alpha$ cut out of the ring so obtained, as shown in Fig. 96. Let $p_{n}$ denote the tangential stress, or hoop stress, acting on this infinitesimal element, $p_{r}$, the radial stress acting on the inner surface $AD$, and $p_{r} + dp_{r}$ the radial stress acting on the outer surface $BC$.

![Fig. 96](https://example.com/fig96.png)

Then the internal and external radii being $r$ and $r + dr$ respectively, the length of $AD$ is $ra$ and of $BC$ is $(r + dr)a$. Since the width of the piece is unity, the resultant radial force acting on the piece, or the difference between the pressure on the inner and outer surfaces, is $(p_{r} + dp_{r})(r + dr)a - p_{r}ra$. Therefore, since the resultant of the hoop stress in a radial direction is $(p_{n}a)dr$, in order that the radial stresses shall equilibrate,

$$ (p_{r} + dp_{r})(r + dr)a - p_{r}ra = p_{n}adr; $$

or, neglecting infinitesimals of an order higher than the second,

$$ p_{r}dr + rdp_{r} = p_{n}dr; $$

which may be written

$$ \frac{d}{dr}(rp_{r}) = p_{n}. $$

(74)
If the ends of the cylinder are free from restraint, or if the cylinder is subjected to a uniform longitudinal stress, the longitudinal deformation must be constant throughout the cylinder. The longitudinal deformation, however, is due to the lateral action of \( p_r \) and \( p_h \), and is of amount \( \frac{p_r}{mE} + \frac{p_h}{mE} \), or \( \frac{1}{mE} (p_r + p_h) \), in which \( m \) denotes Poisson's constant. Therefore, if this expression is constant, \( p_r + p_h \) must be constant, and hence

\[ p_r + p_h = k, \]

where \( k \) is a constant. Consequently, \( p_h = k - p_r \), and substituting this value of \( p_h \) in equation (74) and multiplying by \( r \), it becomes

\[ krdr = 2 rp_r + r^2 dp_r, \]

which may be written

\[ kr = \frac{d}{dr} (r^2 p_r). \]

Integrating,

\[ r^2 p_r = \frac{kr^2}{2} + C_1, \]

in which \( C_1 \) is the constant of integration; whence

\[ (75) \quad p_r = \frac{k}{2} + \frac{C_1}{r^2}. \]

Also, since \( p_h = k - p_r \),

\[ (76) \quad p_h = \frac{k}{2} - \frac{C_1}{r^2}. \]

Now suppose that the cylinder is subjected to a uniform internal pressure of amount \( w_i \) per unit of area, and also to a uniform external pressure of amount \( w_e \) per unit of area. Then \( p_r = w_e \) when \( r = a \), and \( p_r = w_i \) when \( r = b \). Substituting these values in equation (75),

\[ w_e = \frac{k}{2} + \frac{C_1}{a^2}, \quad w_i = \frac{k}{2} - \frac{C_1}{a^2}, \]

whence

\[ C_1 = \frac{a^2b^2(w_e - w_i)}{b^2 - a^2}, \quad k = \frac{2(a^2 w_e - w_i b^2)}{a^2 - b^2}. \]

Therefore, substituting these values of \( C_1 \) and \( k \) in equations (75) and (76), they become

\[ \begin{align*}
  p_r &= \frac{w_e a^2 - w_i b^2}{a^2 - b^2} - \frac{a^2 b^2 (w_e - w_i)}{(a^2 - b^2) a^2}, \\
  p_h &= \frac{w_e a^2 - w_i b^2}{a^2 - b^2} + \frac{a^2 b^2 (w_e - w_i)}{(a^2 - b^2) b^2},
\end{align*} \]

\[ (77) \]
which give the radial and hoop stresses in a thick cylinder subjected to internal and external pressure. Equations (77) are known as Lamé's formulas.

111. Maximum stress in thick cylinder under uniform internal pressure. Consider a thick circular cylinder which is subjected only to internal pressure. Then \( w_t = 0 \), and equations (77) become

\[
\begin{align*}
 p_r &= \frac{w_t b^2}{a^2 - b^2} \left( \frac{a^2}{r^2} - 1 \right), \\
p_h &= -\frac{w_t b^2}{a^2 - b^2} \left( \frac{a^2}{r^2} + 1 \right).
\end{align*}
\]

Since \( p_h \) is negative, the hoop stress in this case is tension.

Since \( p_r \) and \( p_h \) both increase as \( r \) decreases, the maximum stress occurs on the inner surface of the cylinder, where

\[
r = b, \quad p_r = w_i, \quad \text{and} \quad p_h = -\frac{w_i (a^2 + b^2)}{a^2 - b^2}.
\]

Therefore the equivalent stress for a point on the inner surface of the cylinder is

\[
p_e = p_h - \frac{1}{m} p_r = -\frac{w_i (a^2 + b^2)}{a^2 - b^2} - \frac{w_i}{m},
\]

or

\[
p_e = -\frac{w_i}{m (a^2 - b^2)} [(m - 1) b^2 + (m + 1) a^2].
\]

If \( m = 3\frac{1}{3} \), this formula becomes

\[
p_e = -\frac{w_i}{a^2 - b^2} (.7 b^2 + 1.3 a^2).
\]

Problem 134. Find the thickness necessary to give to a steel locomotive cylinder of 22 in. internal diameter, if it is required to withstand a maximum steam pressure of 150 lb./in.\(^2\) with a factor of safety of 10.

Problem 135. In a four-cycle gas engine the cylinder is of steel with an internal diameter of 6 in., and the initial internal pressure is 200 lb./in.\(^2\) absolute.\(^*\) With a factor of safety of 15, how thick should the walls of the cylinder be made?

Problem 136. The steel cylinder of an hydraulic press has an internal diameter of 5 in. and an external diameter of 7 in. With a factor of safety of 3, how great an internal pressure can the cylinder withstand?

\(^*\) By absolute pressure is meant the pressure measured from a vacuum. Absolute pressure therefore includes the atmospheric pressure, which must be deducted from it in order to obtain the effective pressure.
112. Bursting pressure for thick cylinder. Let \( u \) denote the ultimate tensile strength of the material of which the cylinder is composed. Then, from equation (79), the maximum allowable internal pressure \( w_i \) is obtained from the equation
\[
 u = -\frac{w_i}{m(a^2 - b^2)} [(m - 1)b^2 + (m + 1)a^2];
\]
whence
\[
 (81) \quad w_i = \frac{um(a^2 - b^2)}{(m - 1)b^2 + (m + 1)a^2}.
\]
If \( m \) is assumed to be 3\( \frac{1}{3} \), this formula becomes
\[
 (82) \quad w_i = \frac{u(a^2 - b^2)}{.7 b^2 + 1.3 a^2}.
\]
Equations (81) and (82) give the maximum internal pressure \( w_i \) which the cylinder can stand without bursting.

Problem 137. A wrought-iron pipe is 4 in. in external diameter and .25 in. thick. What head of water will it stand without bursting?

Problem 138. Under a water head of 200 ft., what is the factor of safety in the preceding problem?

113. Maximum stress in thick cylinder under uniform external pressure. Consider a thick circular cylinder subjected only to external pressure. In this case \( w_i = 0 \) and equations (77) become
\[
 p_r = \frac{w a^2}{a^2 - b^2} \left(1 - \frac{b^2}{r^2}\right),
\]
\[
 p_h = \frac{w a^2}{a^2 - b^2} \left(1 + \frac{b^2}{r^2}\right).
\]
Since \( p_h \) is positive, the hoop stress in this case is compression.

For a point on the inner surface of the cylinder
\[
 r = b, \quad p_r = 0, \quad \text{and} \quad p_h = \frac{2w a^2}{a^2 - b^2}.
\]
Since the radial stress is zero on the inner surface, the equivalent stress is equal to the hoop stress, that is,
\[
 p_e = \frac{2w a^2}{a^2 - b^2}.
\]

Problem 139. A wrought-iron cylinder is 8 in. in external diameter and 1\( \frac{1}{2} \) in. thick. How great an external pressure can it withstand?
114. Thick cylinders built up of concentric tubes. From equations (77), it is evident that in a thick cylinder subjected to internal pressure the stress is greatest on the inside of the cylinder, and decreases toward the outside. In order to equalize the stress throughout the cylinder and thus obtain a more economical use of material, the device is resorted to of forming the cylinder of several concentric tubes and producing an initial compressive stress on the inner ones. For instance, in constructing the barrel of a cannon, or the cylinder of an hydraulic press, the cylinder is built up of two or more tubes. The outer tubes in this case are made of somewhat smaller diameter than the inner tubes, and then each is heated until it has expanded sufficiently to be slipped over the one next smaller. In cooling, the metal of the outer tube contracts, thus producing a compressive stress in the inner tube and a tensile stress in the outer tube. If, then, this composite tube is subjected to internal pressure, the first effect of the hoop tension thus produced is to relieve the initial compressive stress in the inner tube and increase that in the outer tube. Thus the resultant stress in the inner tube is equal to the difference between the initial stress and that due to the internal pressure, whereas the resultant stress in the outer tube is the sum of these two. In this way the strain is distributed more equally throughout the cylinder. It is evident that the greater the number of tubes used in building up the cylinder, the more nearly can the strain be equalized.

The preceding discussion of the stress in thick tubes can also be applied to the calculation of the stress in a rotating disk. For example, a grindstone is strained in precisely the same way as a thick tube under internal pressure, the load in this case being due to centrifugal force instead of to the pressure of a fluid or gas.
115. Theory of flat plates. The analysis of stress in flat plates is, at present, the most unsatisfactory part of the strength of materials. Although flat plates are of frequent occurrence in engineering constructions, as, for example, in manhole covers, cylinder ends, floor panels, etc., no general theory of such plates has as yet been given. Each form of plate is treated by a special method, which, in most cases, is based upon an arbitrary assumption as to the dangerous section, or the reactions of the supports, and therefore leads to questionable results.

Although the present theory of flat plates is plainly inadequate, it is, nevertheless, of value in pointing out the conditions to which such plates are subject, and furnishing a rational basis for the estimation of their strength. The formulas derived in the following paragraphs, if used in this way, with a clear understanding of their approximate nature, will be found to be invaluable in designing, or determining the strength of flat plates.

The following has come to be the standard method of treatment, and is chiefly due to Bach.*

116. Maximum stress in homogeneous circular plate under uniform load. Consider a flat, circular plate of homogeneous material, which bears a uniform load of amount \( w \) per unit of area, and suppose that the edge of the plate rests freely on a circular rim slightly smaller than the plate, every point of the rim being maintained at the same level. The strain in this case is greater than if the plate was fixed at the edges, and, consequently, the formula deduced will give the maximum stress in all cases.

* For an approximate method of solution see article by S. E. Slocum entitled "The Strength of Flat Plates, with an Application to Concrete-Steel Floor Panels," *Engineering News*, July 7, 1904.
Now suppose a diametral section of the plate taken, and regard either half of the plate as a cantilever (Fig. 97). Then if \( r \) is the radius of the plate, the total load on this semicircle is \( \frac{\pi r^2}{2} w \), and its resultant is applied at the center of gravity of the semicircle, which is at a distance of \( \frac{4r}{3\pi} \) from \( AB \). The moment of this resultant about the support \( AB \) is therefore \( \frac{\pi r^2}{2} \cdot \frac{4r}{3\pi}, \) or \( \frac{2r^3w}{3} \). Similarly, the resultant of the supporting forces at the edge of the plate is of amount \( \frac{\pi r^2}{2} w \), and is applied at the center of gravity of the semi-circumference, which is at a distance of \( \frac{2r}{\pi} \) from \( AB \). The moment of this resultant about \( AB \) is therefore \( \frac{\pi r^2w}{2} \cdot \frac{2r}{\pi}, \) or \( r^2w \). Hence the total external moment \( M \) at the support is

\[
M = r^3w - \frac{2r^3w}{3} = \frac{r^3w}{3}.
\]

Now assume that the stress at any point of the plate is independent of the distance of this point from the center. Under this arbitrary assumption the stress in the plate is given by the fundamental formula in the theory of beams, namely,

\[
p = \frac{Mc}{I}.
\]

If the thickness of the plate is denoted by \( h \), then, since the breadth of the section is \( b = 2r \),

\[
I = \frac{bh^3}{12} = \frac{rh^3}{6}, \quad \text{and} \quad e = \frac{h}{2}.
\]

Consequently,

\[
p = \frac{Mc}{I} = \frac{\frac{r^3w}{3} \cdot \frac{h}{2}}{\frac{rh^3}{6}};
\]

whence

\[
(83) \quad p = w \left( \frac{r}{h} \right)^2.
\]
Föppl has shown that the arbitrary assumption made in deriving this formula can be avoided, and the same result obtained, by a more rigorous analysis than the preceding; and Bach has verified the formula experimentally. Formula (83) is therefore well established both theoretically and practically.

**Problem 140.** The cylinder of a locomotive is 20 in. internal diameter. What must be the thickness of the steel end plate if it is required to withstand a pressure of 160 lb./in.\(^2\) with a factor of safety of 6?

**Problem 141.** A circular cast-iron valve gate \(\frac{1}{2}\) in. thick closes an opening 6 in. in diameter. If the pressure against the gate is due to a water head of 150 ft., what is the maximum stress in the gate?

117. **Maximum stress in homogeneous circular plate under concentrated load.** Consider a flat, circular plate of homogeneous material, and suppose that it bears a single concentrated load \(P\) which is distributed over a small circle of radius \(r_0\) concentric with the plate. Taking a section through the center of the plate and regarding either half as a cantilever, as in the preceding article, the total rim pressure is \(\frac{P}{2}\), and it is applied at a distance of \(\frac{2r}{\pi}\) from the center. The total load on the semicircle of radius \(r_0\) is \(\frac{P}{\pi}\), and it is applied at a distance of \(\frac{4r_0}{3\pi}\) from the section. Therefore the total external moment \(M\) at the section is

\[
M = \frac{Pr}{\pi} - \frac{2Pr_0}{3\pi} = \frac{Pr}{\pi} \left(1 - \frac{2r_0}{3r}\right).
\]

Assuming that the stress is uniformly distributed throughout the plate, the stress due to the external moment \(M\) is given by the formula

\[
p = \frac{Me}{I}.
\]

If the thickness of the plate is denoted by \(h\), then

\[
I = \frac{rh^3}{6} \quad \text{and} \quad e = \frac{h}{2}.
\]

Therefore

\[
p = \frac{Me}{I} = \frac{Pr \left(1 - \frac{2r_0}{3r}\right) h}{\frac{rh^3}{6}};
\]

whence

\[
p = \frac{3P}{\pi h^2} \left(1 - \frac{2r_0}{3r}\right).
\]
If \( r_0 = 0 \), that is to say, if the load is assumed to be concentrated at a single point at the center of the plate, formula (84) becomes

\[
P = \frac{3P}{\pi h^2}.
\]

If the load is uniformly distributed over the entire plate, then \( r_0 = r \) and \( P = \pi r^2 w \), where \( w \) is the load per unit of area. In this case formula (84) becomes

\[
P = \frac{3\pi r^2 w}{\pi h^2} \left( 1 - \frac{2}{3} \right) = w \left( \frac{r}{h} \right)^2,
\]

which agrees with the result of the preceding article.

**Problem 142.** Show that the maximum concentrated load which can be borne by a circular plate is independent of the radius of the plate.

**118. Dangerous section of elliptical plate.** Consider a homogeneous elliptical plate of semi-axes \( a \) and \( b \) and thickness \( h \), and suppose that an axial cross is cut out of the plate, composed of two strips \( AB \) and \( CD \), each of unit width, and intersecting in the center of the plate, as shown in Fig. 98.

Now suppose that a single concentrated load acts at the intersection of the cross and is distributed to the supports in such a way that the two beams \( AB \) and \( CD \) each deflect the same amount at the center. Since \( AB \) is of length \( 2a \), from Article 66, Problem 75, the deflection at the center of \( AB \) is \( D_1 = \frac{P (2a)^3}{48 EI} \). From symmetry, the reactions at \( A \) and \( B \) are equal. Therefore, if each of these reactions is denoted by \( R_1 \), \( 2R_1 = P \), and, consequently,

\[
D_1 = \frac{R_1 a^3}{3 EI}.
\]

Similarly, if \( R_2 \) denotes the equal reactions at \( C \) and \( D \), the deflection \( D_2 \) of \( CD \) at its center is

\[
D_2 = \frac{R_2 b^3}{3 EI}.
\]
If the plate remains intact, the two strips $AB$ and $CD$ must deflect the same amount at the center. Therefore $D_1 = D_2$, and hence

$$\frac{R_1}{R_2} = \frac{b^3}{a^3}. \tag{86}$$

For the beam $AB$ of length $2a$ the maximum external moment is $R_1a$. Also, since $AB$ is assumed to be of unit width, $I = \frac{h^3}{12}$ and $e = \frac{h}{2}$. Hence the maximum stress $p'$ in $AB$ is

$$p' = \frac{Me}{I} = 6 R_1 \frac{a}{h^2}.\]$$

Similarly, the maximum stress $p''$ in $CD$ is

$$p'' = 6 R_2 \frac{b}{h^2}.$$  

Consequently,

$$\frac{p'}{p''} = \frac{R_1a}{R_2b},$$

or, since from equation (86)  \( \frac{R_1}{R_2} = \frac{b^3}{a^3}, \)

$$\frac{p'}{p''} = \frac{b^2}{a^2}.$$  

By hypothesis, $a > b$. Therefore $p'' > p'$; that is to say, the maximum stress occurs in the strip $CD$, or in the direction of the shorter axis of the ellipse. In an elliptical plate, therefore, rupture may be expected to occur along a line parallel to the major axis, a result which has been confirmed by experiment.  

119. Maximum stress in homogeneous elliptical plate under uniform load. The method of finding the maximum stress in an elliptical plate is to consider the two limiting forms of an ellipse, namely, a circle and a strip of infinite length, and express a continuous relation between the stresses for these two limiting forms. The method is therefore similar to that used in Article 85 in obtaining the modified form of Euler's column formula.

Consider first an indefinitely long strip with parallel sides, supported at the edges and bearing a uniform load of amount $\nu$ per unit of area. Let the width of the strip be denoted by $2b$, and its thickness
by \( h \). Then, if this strip is cut into cross strips of unit width, each of these cross strips can be regarded as an independent beam, the load on one of these unit cross strips being \( 2bw \), and the maximum moment at the center being \( \frac{(2b)^2w}{8} \). Consequently, the maximum stress in the cross strips, and therefore in the original strip, is

\[
(87) \quad p = \frac{Me}{I} = \frac{\frac{4}{8} \frac{2}{h^3}}{12} = \frac{3b^2w}{h^3}.
\]

In the preceding article it was shown that the maximum stress in an elliptical plate occurs in the direction of the minor axis. Therefore equation (87) gives the limiting value which the stress in an elliptical plate approaches as the ellipse becomes more and more elongated.

For a circular plate of radius \( b \) and thickness \( h \) the maximum stress was found to be

\[
(88) \quad p = \frac{b^2w}{h^2}.
\]

Comparing equations (87) and (88), it is evident that the maximum stress in an elliptical plate is given, in general, by the formula

\[
p = k \frac{b^2w}{h^2},
\]

where \( k \) is a constant which lies between 1 and 3. Thus, for \( \frac{b}{a} = 1 \), that is, for a circle, \( k = 1 \); whereas, if \( \frac{b}{a} = 0 \), that is, for an infinitely long ellipse, \( k = 3 \). The constant \( k \) may therefore be assumed to have the value

\[
k = 3 - 2 \frac{b}{a},
\]

which reduces to the values 1 and 3 for the limiting cases, and in other cases has an intermediate value depending on the form of the plate. Consequently,

\[
(89) \quad p = \left(3 - 2 \frac{b}{a}\right) \frac{b^2w}{h^3} = \frac{(3a - 2b)b^2w}{ah^3},
\]
which is the required formula for the maximum stress $p$ in a homogeneous elliptical plate of thickness $h$ and semi-axes $a$ and $b$.

**Problem 143.** A cast-iron manhole cover 1 in. thick is elliptical in form, and covers an elliptical opening 3 ft. long and 18 in. wide. How great a uniform pressure will it stand?

**120. Maximum stress in homogeneous square plate under uniform load.** In investigating the strength of square plates the method of taking a section through the center of the plate and regarding the portion of the plate on one side of this section as a cantilever is used, but experiment is relied upon to determine the position of the dangerous section. From numerous experiments on flat plates, Bach has found that homogeneous square plates under uniform load always break along a diagonal.*

Consider a homogeneous square plate of thickness $h$ and side $2a$, which bears a uniform load $w$ per unit of area. Suppose that a diagonal section of this plate is taken, and consider either half as a cantilever, as shown in Fig. 99. Then the total load on the plate is $4wa^2$, and the reaction of the support under each edge is $wa^2$. If $d$ denotes the length of the diagonal $AC$, the resultant pressure on each edge of the plate is applied at a distance $\frac{d}{4}$ from $AC$, and therefore the moment of these resultants about $AC$ is $2(\text{wa}^2)\frac{d}{4}$, or $\frac{\text{wa}^2d}{2}$. The total load on the triangle $ABC$ is $2\text{wa}^2$, and its resultant is applied at the center of gravity of the triangle, which is at a distance of $\frac{d}{6}$ from $AC$. Therefore the moment of the load about $AC$ is $(2\text{wa}^2)\frac{d}{6}$, or $\frac{\text{wa}^2d}{3}$. Therefore the total external moment $M$ at the section $AC$ is

$$M = \frac{\text{wa}^2d}{2} - \frac{\text{wa}^2d}{3} = \frac{\text{wa}^2d}{6}.$$

Hence the maximum stress in the plate is

\[ p = \frac{Me}{I} = \frac{wa^2d}{6\frac{2}{dh^3}}. \]

from which

\[ p = w\left(\frac{a}{h}\right)^{2/3}. \]

The maximum stress in a square plate of side 2\(a\) is therefore the same as in a circular plate of diameter 2\(a\).

**Problem 144.** What must be the thickness of a wrought-iron plate covering an opening 4 ft. square to carry a load of 200 lb./ft\(^2\) with a factor of safety of 5?

121. **Maximum stress in homogeneous rectangular plate under uniform load.** In the case of rectangular plates experiment does not indicate so clearly the position of the dangerous section as it does for square plates. It will be assumed in what follows, however, that the maximum stress occurs along a diagonal of the rectangle. This assumption is at least approximately correct if the length of the rectangle does not exceed two or three times its breadth.

Let the sides of the rectangle be denoted by 2\(a\) and 2\(b\), and the thickness of the plate by \(h\) (Fig. 100). Also let \(d\) denote the length of the diagonal \(AC\), and \(c\) the altitude of the triangle \(ABC\). Now suppose that a diagonal section \(AC\) of the plate is taken, and consider the half plate \(ABC\) as a cantilever, as shown in Fig. 100. If \(w\) denotes the unit load, the total load on the plate is 4\(abw\), and consequently the resultant of the reactions of the supports along \(AB\) and \(BC\) is of amount 2\(abw\), and is applied at a distance \(c/2\) from \(AC\). Therefore the moment of the supporting force about \(AC\) is \(abuc\). Also, the total load on the triangle
$ABC$ is $2\ abw$, and it is applied at the center of gravity of the triangle, which is at a distance of $\frac{c}{3}$ from $AC$. Consequently, the total moment of the load about $AC$ is $\frac{2\ abwc}{3}$. Therefore the total external moment $M$ at the section $AC$ is

$$M = abwc - \frac{2\ abwc}{3} = \frac{abwc}{3},$$

and the maximum stress in the plate is

$$p = \frac{Me}{I} = \frac{abwc \cdot h}{\frac{3}{2} \ dh^3} = \frac{2\ wabc}{dh^2},$$

or, since $cd = 4\ ab$,

$$p = \frac{w \ c^2}{2\ h^3},$$

(91)

which gives the required maximum stress.

For a square plate $a = b$ and $c = a \sqrt{2}$, and formula (91) reduces to formula (90) for square plates, obtained in the preceding article.

Problem 145. A wrought-iron trapdoor is 5 ft. long, 3 ft. wide, and $\frac{3}{8}$ in. thick. How great a uniform load will it bear?

122. Non-homogeneous plates; concrete-steel floor panels. The formulas derived in the preceding articles apply only to flat plates of homogeneous material. If a plate is composed of non-homogeneous material, such as reïnforced concrete, the maximum stress is given by the formula

$$p = \frac{Me'}{I'},$$

where $I'$ is the moment of inertia of the equivalent homogeneous section obtained from the non-homogeneous section as explained in Article 48, and $e'$ is the distance of the extreme fiber of this equivalent homogeneous section from its neutral axis.

Thus, from Article 116, the external moment $M$ on half of a uniformly loaded circular plate is $M = \frac{r^2w}{3}$, and, consequently, the maximum stress in a uniformly loaded, non-homogeneous, circular plate is given by the formula

(92)

$$p = \frac{r^2we'}{3\ I'},$$
where $I'$ and $e'$ refer to the equivalent homogeneous section as explained above, and this section is taken through the center of the plate.

Similarly, from Article 120, the maximum stress in a uniformly loaded, non-homogeneous, square plate of side $2\ a$ is given by the formula

$$p = \frac{\sqrt{2}}{3} \cdot \frac{wa^b\ e'}{I'};$$

and, from Article 121, the maximum stress in a uniformly loaded, non-homogeneous, rectangular plate of sides $2\ a$ and $2\ b$ by the formula

$$p = \frac{ab\ wce'}{3\ I'};$$

in which $e'$ and $I'$ refer to the equivalent homogeneous section obtained from a diagonal section of the plate.

**Problem 146.** A concrete-steel floor panel is 18 ft. long, 15 ft. wide, and 4 in. thick, and is reinforced by square wrought-iron rods 1 in. thick, placed $\frac{1}{3}$ of an inch from the bottom of the slab and spaced 1 ft. apart. Find the maximum stress in the panel under a total live and dead load of 150 lb./ft.$^2$.

**Note.** Take a diagonal section of the panel and calculate the equivalent homogeneous section corresponding to it. Then find the position of the neutral axis of this equivalent homogeneous section, and its moment of inertia about this neutral axis, as explained in Article 48. The maximum stress can then be obtained from formula (94).

**Problem 147.** Design a floor panel 14 ft. square, to be made of reinforced concrete and to sustain a total uniform load of 120 lb./ft.$^2$ with a factor of safety of 4.
CHAPTER IX

CURVED PIECES: HOOKS, LINKS, AND SPRINGS

123. Erroneous analysis of hooks and links. In calculating the strength of a curved piece whose axis is a plane curve, such as a hook or a link of a chain, many engineers are accustomed to assume that the distribution of stress is the same as in a straight beam subjected to an equal bending moment and axial load. For example, in calculating the strength of a hook, such as shown in Fig. 101, the practice has been to take a section \( AB \) where the bending moment is a maximum, and calculate the unit stress \( p \) on \( AB \) by the formula

\[
p = \frac{P}{F} + \frac{(Pd)e}{I},
\]

where the first term denotes the direct stress on the section \( AB \) of area \( F \), and the second term represents the bending stress due to a moment \( Pd \) calculated from the formula for straight beams.

The bending formula for straight beams, however, does not apply to curved pieces, as will be shown in what follows. Moreover, experiment has conclusively shown that a curved piece breaks at the point of sharpest curvature, whereas the above formula takes no account whatever of the curvature. The above formula is therefore not even approximately correct, and is cited as a popular error against which the student is warned.

124. Bending strain in curved piece. Consider a curved piece which is subjected to pure bending strain, and assume that the axis of the piece is a plane curve and also that the radius of curvature is not very large as compared with the thickness of the piece. Hooke's law and Bernoulli's assumption will be taken as the starting point.
for the analysis of stress, as in the theory of straight beams; that is to say, it will be assumed that the stress is proportional to the deformation produced, and that any plane section remains identical with itself during the deformation.

Since the fibers on the convex side are longer than those on the concave side, it will take less stress to deform them an equal amount. Therefore the neutral axis does not pass through the center of gravity $G$ of the section, but through some other point $D$, below $G$, as shown in Fig. 102. For if the neutral axis passed through $G$, the total deformation above and below $G$ would be of equal amount, and therefore the total stress above $G$ would be less than that below $G$, since the fibers above $G$ are longer than those below. This shifting of the neutral axis constitutes the fundamental difference between the theory of straight and curved pieces.

Now let the length of any fiber, such as $MN$ in Fig. 102, be denoted by $l$, and the distance of this fiber from a gravity axis $GZ$ by $y$. Also, let $\rho$ denote the radius of curvature $OG$ of the piece, $\beta$ the angle between two plane sections, and $\alpha$ the angle of deformation of a plane section. Then

$$l = \beta \cdot MO = (OG + GN)\beta = (\rho + y)\beta,$$

and the deformation $dl$ of the fiber $MN$ is

$$dl = NN' = \alpha \cdot ND = (y + d)\alpha,$$

where $d$ denotes the distance $GD$ between the neutral axis and the gravity axis. From Hooke’s law,

$$\frac{dl}{l} = \frac{p}{E},$$

whence

$$p = \frac{Edl}{l} = \frac{E(y + d)\alpha}{(\rho + y)\beta}.$$

Let $\frac{\alpha}{\beta} = k$, where $k$ is a constant. Then this expression for $p$ reduces to
(95) \[ p = E k \frac{y + d}{y + \rho}. \]

Under the assumption of pure bending strain the shear is zero and the normal stresses form a couple. Therefore the algebraic sum of the normal stresses is zero; that is to say,

\[ \int p dF = 0, \]

or, substituting the value of \( p \) from equation (95),

\[ kE \int \frac{y + d}{y + \rho} dF = 0. \]

Since \( k \) and \( E \) are constants and not zero, the integral must be zero. Therefore, separating the integral into parts,

\[ \int \frac{ydF}{y + \rho} + d \int \frac{dF}{y + \rho} = 0; \]

whence

(96) \[ d = - \frac{\int \frac{ydF}{y + \rho}}{\int \frac{dF}{y + \rho}}, \]

which gives the distance of the neutral axis below the center of gravity of the section.

Now let \( M \) denote the external bending moment acting on any given section of area \( F \), \( dF \) an infinitesimal area taken anywhere in this section, \( p \) the stress acting on it, and \( y \) its distance from the gravity axis \( GZ \). Then

\[ \int (y + d)p dF = M, \]

or, substituting the value of \( p \) from equation (95),

\[ E k \int \frac{(y + d)^2}{y + \rho} dF = M; \]

consequently

\[ k = \frac{M}{E \int \frac{(y + d)^2}{y + \rho} dF}, \]

and hence

(97) \[ p = E k \frac{y + d}{y + \rho} = \frac{M(y + d)}{(y + \rho) \int \frac{(y + d)^2}{y + \rho} dF}, \]
which is the required formula for calculating the bending stress at any point of a curved piece.

125. Simplification of formula for unit stress. In formulas (96) and (97), derived in the preceding article, the integrals involved make the formulas difficult of application. The following geometrical transformation, which is due to Résal,* greatly simplifies the formulas and their application.

The first step is a geometrical transformation of the boundary of the given cross section. Consider a symmetrical cross section, for example the circle shown in Fig. 103, and let $OY$ be an axis of symmetry passing through the center of curvature $C$ of the section, and $OZ$ a gravity axis perpendicular to $OY$. Now suppose radii drawn from $C$ to each point $M$ in the boundary of the cross section. From $H$, the point of intersection of $CM$ with the gravity axis $OZ$, erect a perpendicular to $OZ$, and from $M$ draw a perpendicular to $OY$. Then these two perpendiculars will intersect in a point of the transformed boundary, as shown in Fig. 103.

It will now be proved (1) that the distance of the center of gravity $G$ of the transformed section from the center of gravity $O$ of the original section is the value of $d$ given by formula (96), and (2) that the moment of inertia of the transformed section is the integral which occurs in formula (97).

In Fig. 103 the distance $NM'$ is the $Z$-coördinate of the point $M'$; let it be denoted by $z'$. Then

$$NM' = z' = OH = MN \frac{CO}{CN} = z \frac{\rho}{\rho + y}.$$

The distance $d'$ of the center of gravity $G$ of the transformed

* Résistance des Matériaux, pp. 385 et seq.
section below the center of gravity $O$ of the original section is

$$d' = OG = - \frac{\int z'y dy}{\int z'dy} = - \frac{\int zy \frac{\rho}{\rho + y} dy}{\int z \frac{\rho}{\rho + y} dy}.$$  

Dividing out the constant $\rho$ and replacing the element of area $zdy$ by $dF'$, this expression for $d'$ becomes

$$d' = - \frac{\int \frac{ydF'}{y + \rho}}{\int \frac{dF'}{y + \rho}},$$

which is identical with the value of $d$ given by formula (96) above. Consequently, the neutral axis of the original cross section coincides with the gravity axis of the transformed section.

Now let the moment of inertia of the transformed section be denoted by $I'$. Then

$$I' = \int y'^2 dF',$$

in which $y'$ is measured from the gravity axis of the transformed section, that is, from a line through $G$ parallel to $OZ$; and $dF'$ denotes an element of area of the transformed section; whence $dF' = z'dy'$. Therefore, since

$$y' = y + d, \quad z' = z \frac{\rho}{\rho + y}, \quad \text{and} \quad dy' = dy,$$

the expression for $I'$ becomes

$$I' = \int (y + d)^2 \left( z \frac{\rho}{\rho + y} \right) dy;$$

or, if the element of area $zdy$ is denoted by $dF$,

$$I' = \rho \int \frac{(y + d)^2 dF'}{y + \rho}.$$

This integral, however, is the one which occurs in formula (97). Consequently, if its value from the above equation is substituted in (97), the expression for the unit stress $p$ simplifies into

$$p = \frac{M\rho}{I'} \frac{y + d}{y + \rho}. \quad (98)$$
The bending stress on any cross section can easily be found geometrically from formula (98) by carrying out the following directions.

1. Plot the given cross section and transform its boundary into a new section, as explained at the beginning of this article.

2. Determine the position of the center of gravity and calculate the moment of inertia of this transformed section by the graphical method given in Article 47, Chapter III.

3. Substitute the values of \( d \) and \( I' \) found by this method, and also the given values of \( M, p, \) and \( y \) in formula (98).

It is to be noted that formula (98) gives the unit stress due to pure bending strain only. In the case of a hook or link there is also a direct stress to be added to the above, of amount \( \frac{P}{F} \) where \( P \) is the total axial load and \( F \) is the area of the cross section (compare Article 123).

**Problem 148.** The wrought-iron crane hook, shown in Fig. 104, is designed to support a load of ten tons. Find the maximum stress in the hook under this load, and thence determine the factor of safety.

**Solution.** Let a cross section \( OCY \) of the hook be taken at the position of maximum moment, as shown in the shaded projection in Fig. 104.

In Fig. 105 let the curve numbered 1 represent this projection. The gravity axis \( DF \) of this section, perpendicular to the axis of symmetry \( OCY \), is first determined, which may be done by the graphical method explained in Article 47, or otherwise.* Curve 1 is then transformed into curve 2 by the method explained at the beginning of Article 125, the light construction lines on the left of \( OY \) showing how this is accomplished.

The moment of inertia \( I' \) of curve 2 is then found graphically by the method explained in Article 47. This method consists in first transforming curve 2 into curves 3 and 4, as there explained, then measuring the areas between \( OY' \) and curves 3 and 4 by means of a planimeter, and finally substituting the areas so found in the formulas for the moment of inertia \( I' \) of curve 2 and the distance \( c \) of its center of gravity from \( AB \), given in Article 47.

* A simple method of determining a gravity axis which is sufficiently accurate for all ordinary purposes consists in cutting the section out of cardboard and balancing it on a knife edge.
In the present case \( p = CE = 4.4" \), and the distance from the line of action of the load to the neutral axis of the section is

\[
c + OC = 1.79" + 2.22" = 4.01";
\]

consequently the external moment \( M \) acting on the section is

\[
M = 20,000 \times 4.01 = 80,200 \text{ in. lb.}
\]

The fiber most distant from the neutral axis is at the back of the hook. The quantity \( y \) in formula (98) is the distance of this extreme fiber from the gravity axis of the original section; hence \( y = 2.8" \). Also the distance \( d \) between the gravity axis of the original cross section 1 and that of the transformed section 2 is \( d = .40" \). Substituting these values of \( M, I, p, d, \) and \( y \) in formula (98), Article 125, the maximum bending stress \( p \) in the hook is found to be

\[
p = 11,123 \text{ lb./in.}^2.
\]

To this must be added the direct stress on the section, which is found by dividing the load by the area of the section. Consequently, the maximum total stress is

\[
11,123 + 5102 = 16,225 \text{ lb./in.}^2.
\]

Since the ultimate strength of wrought iron in tension may be taken as 54,000 lb./in.\(^2\), the factor of safety is about 3.1.

**Problem 149.** By the formula given in Article 123, calculate the maximum bending stress and the maximum total stress on the hook shown in Fig. 104, and compare the results with those of the preceding problem.

**Note.** The lever arm of the force in this formula is assumed to be the distance from the axis of the hook to the center of gravity of the original cross section, or the distance \( CE \) in Fig. 105. Hence, in this case,

\[
M = 20,000 \times 4.4 = 88,000 \text{ in. lb.}
\]
Problem 150. The dangerous section of a hook similar to that shown in Fig. 104 has for its dimensions \( b = 2\frac{1}{2}'' \), \( h = 6'' \), \( r_1 = 1\frac{1}{2}'' \), \( r_2 = \frac{1}{6}'' \), and \( OC = 2\frac{1}{2}'' \) (Fig. 106). Using a factor of safety of 4, find the safe load for the hook.

* 126. Curved piece of rectangular cross section. If the cross section of a curved piece is rectangular, the integrals in formulas (96) and (97), Article 124, can be easily evaluated. These formulas may therefore be used for calculating the strength of the piece in preference to the graphical method explained in the preceding article.

Let the cross section of the piece be a rectangle of breadth \( b \) and depth \( h \), and let \( \rho \) denote the radius of curvature of the piece at the section under consideration. From formula (96), the distance of the neutral axis of the section from the mean fiber, or gravity axis, is

\[
d = - \frac{\int y \, dF}{\int \frac{dF}{y + \rho}},
\]

where \( y \) denotes the distance of the infinitesimal area \( dF \) from the gravity axis. In the present case \( dF = bdy \); hence

\[
d = - \frac{\int_{-\frac{h}{2}}^{\frac{h}{2}} y \, dy}{\int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{dy}{y + \rho}} = - \frac{\int_{-\frac{h}{2}}^{\frac{h}{2}} y \, dy}{\int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{dy}{y + \rho}}.
\]

By division, \( \frac{y}{y + \rho} = 1 - \frac{\rho}{y + \rho} \). Consequently, the numerator of the above fraction becomes

\[
\int_{-\frac{h}{2}}^{\frac{h}{2}} y \, dy = \int_{-\frac{h}{2}}^{\frac{h}{2}} dy - \rho \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{dy}{y + \rho} = [y - \rho \log_e (y + \rho)]_{-\frac{h}{2}}^{\frac{h}{2}}
\]

\[
= h - \rho \log_e \frac{2 \rho + h}{2 \rho - h}.
\]

* For a brief course the remainder of this chapter may be omitted.
Similarly, the denominator becomes

$$\int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{dy}{y + \rho} = \log_e (y + \rho) \bigg|_{-\frac{h}{2}}^{\frac{h}{2}} = \log_e \frac{2 \rho + h}{2 \rho - h}.$$  

Consequently,

$$d = \frac{h - \rho \log_e \frac{2 \rho + h}{2 \rho - h}}{\log_e \frac{2 \rho + h}{2 \rho - h}},$$

which may be written

$$d = \rho - \frac{h}{\log_e \frac{2 \rho + h}{2 \rho - h}}.$$  

(99)

From formula (97), Article 124, the unit stress \(p\) at any point in the cross section, distant \(y\) from the mean fiber, is given by the equation

$$p = \frac{M(y + d)}{(y + \rho) \int \frac{(y + d)^2}{y + \rho} dF}.$$  

Replacing \(dF\) by \(bdy\), and separating the integral in the denominator into partial integrals by means of division, this integral becomes

$$\int \frac{(y + d)^2}{y + \rho} dF = \int \frac{(y^2 + 2 dy + d^2)}{y + \rho} bdy$$

$$= b \left[ \int_{-\frac{h}{2}}^{\frac{h}{2}} y dy + \int_{-\frac{h}{2}}^{\frac{h}{2}} (2 d - \rho) dy + \int_{-\frac{h}{2}}^{\frac{h}{2}} \frac{(d - \rho)^2 dy}{y + \rho} \right]$$

$$= b \left[ \frac{y^2}{2} + (2 d - \rho) y + (d - \rho)^2 \log_e (y + \rho) \right]_{-\frac{h}{2}}^{\frac{h}{2}}$$

$$= b \left[ (2 d - \rho) h + (d - \rho)^2 \log_e \frac{2 \rho + h}{2 \rho - h} \right].$$

Substituting for \(d\) its value from equation (99), this expression finally reduces to

$$\int \frac{(y + d)^2}{y + \rho} dF = bh \left[ \rho - \frac{h}{\log_e \frac{2 \rho + h}{2 \rho - h}} \right] = bhd.$$
Hence the expression for $p$ becomes

$$P = \frac{M (y + d)}{(y + \rho) bhd}.$$  \hspace{1cm} (100)

The maximum stress is the value of $p$ for $y = \frac{h}{2}$. Consequently,

$$P_{\text{max}} = \frac{M (h + 2d)}{(h + 2\rho) bhd}.$$  \hspace{1cm} (101)

From this formula, it is evident that the stress is greatest where the radius of curvature is least, a result which is amply verified by experience, as mentioned in the following article.

**Problem 151.** A boat’s davits are composed of two wrought-iron bars $2\frac{1}{2}$ in. square, bent to a radius of 2 ft., as shown in Fig. 107. If the boat weighs 500 lb. and is hung 3$\frac{1}{2}$ ft. from the vertical axis of the davits, find the maximum stress in the davits and the factor of safety.

127. **Effect of sharp curvature on bending strength.** Consider a sharply curved prismatic piece which is subjected to bending strain. From the above discussion, it is known that for a section taken in the neighborhood of the bend, the neutral axis does not coincide with the gravity axis but approaches the center of curvature. The neutral fiber is therefore separated from the mean fiber, or axis of the piece, and takes some such position as that shown by the broken line in Fig. 108. Consequently the inner fiber through $A$ must endure a far greater stress than that deduced from formulas for the straight portion. Engineers and constructors have learned by experience that sharp curvature produces weakness of this kind, and that it is necessary to reinforce a piece at a bend either by increasing its diameter or by adding a brace.

As an illustration of the effect of sharp curvature on bending strength, suppose that a bar of rectangular cross section is bent into a right angle, as shown in Fig. 109. In this case the center of curvature
of the mean fiber $BC$ is at $A$. Therefore, if $h$ denotes the thickness of the piece, the radius of curvature of $BC$ is $\rho = \frac{h}{2}$. Consequently,

$$\log_e \frac{2\rho + h}{2\rho - h} = \log_e \frac{2h}{0} = \infty,$$

and hence formula (99) becomes

$$d = \rho = \frac{h}{2}.$$

Therefore the neutral fiber passes through the vertex of the angle $A$, and consequently a piece of this kind can offer no resistance to bending. In other words, if a piece is bent exactly at right angles on itself, the slightest bending strain must produce incipient rupture.

This example is useful, then, in pointing out the danger of sharp curvature and showing how rapidly the strength decreases with the radius of curvature.

128. Maximum moment in circular piece. Consider a prismatic piece with a circular axis, such as a ring or a section of pipe, and suppose that it is subjected to two equal and opposite forces $P$, either of tension or compression, acting along a diameter as shown in Fig. 110. Draw a second diameter $MN$ at right angles to the direction in which the forces $P$ act. Since these two diameters divide the figure into four symmetrical parts, it is only necessary to consider one of these parts, say the upper left-hand quadrant. The forces acting on any section of this quadrant consist of a single force and a moment.

On the base $CD$ of the quadrant this single force is of amount $\frac{P}{2}$,
and the unknown moment will be denoted by $M_0$. On any other section $AB$ the bending moment $M$ and single force $P'$ are respectively

$$M = M_0 + \frac{P}{2} (\rho - \rho \cos \beta),$$

$$P' = \frac{P}{2} \cos \beta,$$

in which $\rho$ is the radius of the mean fiber and $\beta$ is the angle which the plane of the section $AB$ makes with the base $CD$.

Now, no matter whether the section is flattened or elongated by the strain, from the symmetry of the figure the diametral sections $MN$ and $PP$ will always remain at right angles to one another. Therefore the total angular deformation $\Delta \beta$ for the quadrant under consideration must be zero; that is to say,

$$\int_0^{\pi/2} \Delta \beta = 0.$$

But, from Article 66,

$$\Delta \beta = \frac{M ds}{EI}.$$

Consequently,

$$\int_0^{\pi/2} \frac{M ds}{EI} = 0.$$

Inserting in this expression the value of $M$ obtained above,

$$\int_0^{\pi/2} \left( M_0 + \frac{P \rho}{2} - \frac{P \rho}{2} \cos \beta \right) \frac{d\beta}{EI} = 0,$$

or

$$\int_0^{\pi/2} \left( M_0 + \frac{P \rho}{2} - \frac{P \rho}{2} \cos \beta \right) d\beta = M_0 \frac{\pi}{2} + \frac{P \rho \pi}{4} - \frac{P \rho}{2} = 0;$$

whence

$$M_0 = -\frac{\pi - 2}{2 \pi} P \rho = -0.182 P \rho,$$

which is the maximum negative moment.

From formula (102), the maximum positive moment must occur when $\cos \beta = 0$, that is, when $\beta = \frac{\pi}{2}$, or at top and bottom. Therefore

$$M_{\max} = M_{\frac{\pi}{2}} = \frac{P \rho}{\pi} = 0.318 P \rho.$$
The maximum moment, therefore, occurs at the points of application of the forces. From formula (102), the direct stress at these points is zero.

Having determined the position and amount of the maximum bending moment, the maximum bending stress can be calculated by the graphical method explained in Article 125, or, if the piece is rectangular in section, by formulas (99) and (100) or (101) in Article 126.

Problem 152. A wrought-iron anchor ring is 6 in. in inside diameter and 2 in. in sectional diameter. With a factor of safety of 4, find by the graphical method of Article 125 the maximum pull which the ring can withstand.

Problem 153. A cast-iron pipe 18 in. in internal diameter and 1 in. thick is subjected to a pressure of 150 lb./linear foot at the highest point of the pipe. Find the maximum stress in the pipe.

Hint. Use formula (101), Article 126.

129. Plane spiral springs. Consider a plane spiral spring, such as the spring of a clock or watch. Let $P$ denote the force tending to wind up the spring, and $c$ the perpendicular distance of $P$ from the spindle on which the spring is wound (Fig. 111). Also, let $dx$ denote a small portion of the spring at any point $A$ distant $y$ from $P$. Then the moment at $A$ is $M = Py$; and hence, from Article 66, the angular deformation $d\beta$ for the portion $dx$ is given by the formula

$$d\beta = \frac{Mdx}{EI} = \frac{Pydx}{EI}.$$ 

Therefore the total angular deformation of the spring is

$$\beta = \int_0^l d\beta = \int_0^l \frac{Pydx}{EI} = \frac{P}{EI} \int_0^l ydx.$$ 

Since the average value of $y$ is $c$, and the integral of $dx$ is the length of the spring $l$,

$$\int_0^l ydx = cl,$$

and hence

$$\beta = \frac{Pcl}{EI}.$$
The resilience $W$ of the spring is, therefore,

$$W = \frac{1}{2} M\beta = \frac{P^2 c^2 l}{2 EI}.$$ 

If the spring is of rectangular cross section, which is the usual form for plane spiral springs, the stress can be calculated by formulas (99) and (101), Article 126.

Problem 154. A steel clock spring $\frac{3}{4}$ in. wide and $\frac{1}{3}$ in. thick is wound on a spindle $\frac{3}{8}$ in. in diameter. With a factor of safety of 5, what is the maximum moment available for running the mechanism?

Suggestion. The dangerous section occurs at the spindle where the moment is greatest and the radius least. Therefore, in the present case, $\rho = \frac{3}{8}$ in., $h = \frac{1}{3}$ in., $b = \frac{3}{4}$ in.; and from Article 22, $p_{\text{max}} = \frac{240,000}{5} = 48,000$ lb./in.$^2$. $d$ can then be calculated by formula (99), and $M$ by formula (101).
CHAPTER X

ARCHES AND ARCHED RIBS

I. Graphical Analysis of Forces

130. Composition of forces. In determining the effect which a given system of forces has upon a body, it is often convenient to represent the forces by directed lines and calculate the result graphically. In this method of representation the length of the line denotes the magnitude of the force laid off to any given scale, and the direction of the line indicates the direction in which the force acts, or its line of action.

When the lines of action of a system of forces all pass through the same point, the forces are said to be concurrent. The simplest method of dealing with such a system is to find the amount and line of action of a single force which would have the same effect as the given system of forces upon the motion of the point at which they act. This single force is called the resultant of the given system. When each of a system of forces acting on a body balances the others so that the body shows no tendency to move, the forces are said to be in equilibrium, and in this case it is obvious that their resultant must be zero.

The resultant of two forces acting at a point is found by drawing the forces to scale in both magnitude and direction, and constructing a parallelogram upon these two lines as adjacent sides; the diagonal of this parallelogram is then the required resultant (Fig. 112). This construction can be verified experimentally by fastening a string at two points $A$ and $B$ and suspending a weight $R$ from it at any point $C$ (Fig. 113). Then if two forces equal in magnitude to the tension in $AC$ and $BC$ are laid off parallel to $AC$ and $BC$
respectively, it will be found that their resultant, obtained by the above construction, is equal and parallel to $R$.

Since the opposite sides of a parallelogram are equal and parallel, it is more convenient in finding the resultant of two forces to construct half the parallelogram. Thus, in the preceding example, if $P_3$ is laid off from the end of $P_1$, $R$ is the closing side of the triangle so formed (Fig.114). Such a figure is called a force triangle.

In order to find the resultant of several concurrent forces lying in the same plane, it is only necessary to combine two of them into a single resultant, combine this resultant with a third force, and so on, taking the forces in order around the point in which they meet. Thus, in Fig. 115, $R_1$ is the resultant of $P_1$ and $P_2$; $R_2$ is the resultant of $R_1$ and $P_3$; $R_3$ is the resultant of $R_2$ and $P_4$; and $R$ is the resultant of $R_3$ and $P_5$. $R$ is therefore the resultant of the entire system $P_1, P_2, P_3, P_4, P_5$.

In carrying out this construction it is unnecessary to draw the intermediate resultants $R_1, R_2,$ and $R_3$, the final resultant in any case being the closing side of the polygon formed by placing the forces end to end in order. Such a figure is called a force polygon. From the above construction it is evident that the necessary and sufficient condition that a system of concurrent forces shall be in equilibrium is that their force polygon shall close, since in this case their resultant must be zero.
The resultant of a system of non-concurrent forces lying in the same plane, that is to say, forces whose lines of action do not all pass through the same point, is found by means of a force polygon as explained above. In this case, however, the closing of the force polygon is not a sufficient condition for equilibrium, for the given system may reduce to a pair of equal and opposite forces acting in parallel directions, called a couple, which would tend to produce rotation of the body on which they act. For non-concurrent forces, therefore, the necessary and sufficient conditions for equilibrium are first, the resultant of the given system must be zero, and second, the sum of the moments of the forces about any point must be zero.

Suppose that the force polygon corresponding to any given system of forces is projected upon two perpendicular lines, say a vertical and a horizontal line. Then since the sum of the projections upon any line of all the sides but one of a polygon is equal to the projection of this closing side upon the given line, the sum of the horizontal projections of any system of forces is equal to the horizontal projection of their resultant, and the sum of their vertical projections is equal to the vertical projection of their resultant (Fig. 116).

The conditions for equilibrium of a system of forces lying in the same plane may then be reduced to the following convenient form.

1. For equilibrium against translation,

\[
\begin{align*}
\sum \text{horizontal components} &= 0, \\
\sum \text{vertical components} &= 0.
\end{align*}
\]

2. For equilibrium against rotation,

\[
\sum \text{moments about any point} = 0.
\]

If the forces are concurrent, rotation cannot occur, and the first condition alone is sufficient to assure equilibrium. In order that
a system of non-concurrent forces shall be in equilibrium, however, both conditions must be fulfilled.

Problem 155. Construct the resultant of the system of concurrent forces shown in Fig. 117.

Problem 156. Determine whether or not the system of parallel forces shown in Fig. 118 satisfies conditions 1 and 2 above.

131. Equilibrium polygon. The preceding construction for

the force polygon gives a method for calculating the magnitude and direction of the resultant of any given system of forces, but does not determine the line of action of their resultant. The most convenient way to determine the line of action of the resultant is to introduce into the given system two equal and opposite forces of arbitrary amount and direction, such as $P'$ and $P''$ in Fig. 119 (A).

Since $P'$ and $P''$ balance one another, they will not affect the equilibrium of the given system. This is obvious from the force polygon. For in Fig. 119 (B), let $R$ denote the resultant of the given system of forces $P_1 \cdots P_4$. Then, if $OA$ represents in magnitude and direction the arbitrary force $P'$, $OB$
is the resultant of $P'$ and $P_1$, $OC$ is the resultant of $OB$ and $P_2$, etc., and finally $OE$, or $P'''$, represents the resultant of $P'$, $P_3$, $P_2$, $P_3$, $P_4$. If then $P'''$ is combined with $P''$, the resultant $R$ is obtained as before.

Now to find the line of action of $R$, suppose that $P''$ and $P_1$ are combined into a resultant $R_1$ acting in the direction $A'B'$ (Fig. 119 (C)) parallel to the ray $OB$ of the force polygon (Fig. 119 (B)). Prolong $A'B'$ until it intersects $P_2$, and then combine $R_1$ and $P_2$ into a resultant $R_2$ acting in the direction $B'C'$ parallel to the ray $OC$ of the force polygon. Continue in this manner until $P'''$ is obtained. Then the resultant of $P''$ and $P'''$ will give both the magnitude and line of action of the resultant of the original system $P_1$, $P_2$, $P_3$, $P_4$. The closed figure $A'B'C'D'E'F''$ obtained in this way is called an equilibrium polygon.

For a system of parallel forces the equilibrium polygon is constructed in the same manner as above, the only difference being that in this case the force polygon becomes a straight line, as shown in Fig. 120.

Since $P''$ and $P'''$ are entirely arbitrary both in magnitude and direction, the point $O$, called the pole, may be chosen anywhere in the plane. Therefore, in constructing an equilibrium polygon corresponding to any given system of forces, the force polygon $ABCD$ (Fig. 119) is first drawn, then any convenient point $O$ is chosen and joined to the vertices $A$, $B$, $C$, $D$, $E$ of the force polygon, and finally the equilibrium polygon is constructed by drawing its sides parallel to the rays $OA$, $OB$, $OC$, etc., of the force diagram.
Since the position of the pole \( O \) is entirely arbitrary, there is an infinite number of equilibrium polygons corresponding to any given set of forces. The position and magnitude of the resultant \( R \), however, is independent of the choice of the pole, and will be the same, no matter where \( O \) is placed.

**Problem 157.** The ends of a cord are fastened to supports and weights attached at different points of its length. Show that the position assumed by the string is the equilibrium polygon for the given system of loads.

132. **Application of equilibrium polygon to determining reactions.** One of the principal applications of the equilibrium polygon is in determining the unknown reactions of a beam or truss. To illustrate its use for this purpose, consider a simple beam placed horizontally and bearing a number of vertical loads \( P_1, P_2, \text{etc.} \) (Fig. 121). To determine the reactions \( R_1 \) and \( R_2 \), the force diagram is first constructed by laying off the loads \( P_1, P_2, \text{etc.} \), to scale on a line \( AF \), choosing any convenient point \( O \) as pole and drawing the rays \( OA, OB, \text{etc.} \). The equilibrium polygon corresponding to this force diagram is then constructed, starting from any point, say \( A' \), in \( R_1 \).

Now the closing side \( A'G' \) of the equilibrium polygon determines the line of action of the resultants \( P' \) and \( P'' \) at \( A' \) and \( G' \) respectively. For a simple beam, however, the reactions are vertical. Therefore, in order to find these reactions each of the forces \( P' \) and \( P'' \) must be resolved into two components, one of which shall be vertical. To accomplish this, suppose that a line \( OH \) is drawn from the pole \( O \) in
the force diagram parallel to the closing side $A'G'$ of the equilibrium polygon. Then $OH$ (or $P'$) may be replaced by its components $AH$ and $AO$, parallel to $R_1$ and $A'B'$ respectively; and similarly, $OH$ may be replaced by its components $FH$ and $OF$, parallel to $R_2$ and $F'G'$ respectively. $HA$ and $FH$ are therefore the required reactions.

**Problem 158.** A simple beam 20 ft. long supports concentrated loads of 3, 5, 2, and 9 tons at distances of 5, 7, 14, and 18 ft. respectively from the left support. Calculate the reactions of the supports graphically.

**Problem 159.** Construct an equilibrium polygon for a simple beam bearing a uniform load, and show that the reactions are equal.

**133. Equilibrium polygon through two given points.** Let it be required to pass an equilibrium polygon through two given points, say $M$ and $N$ (Fig. 122).

To solve this problem a trial force diagram is first drawn with any arbitrary point $O$ as pole, and the corresponding equilibrium polygon $MA'B'C'D'E'$ constructed, starting from one of the given points, say $M$. The reactions are then determined by drawing a line $OH$ parallel to the closing side $ME'$ of the equilibrium polygon, as explained in the preceding article.

The reactions, however, are independent of the choice of the pole in the force diagram, and consequently they must be of amount $AH$ and $HE$, no matter where $O$ is placed. Moreover, if the equilibrium polygon is to pass through both $M$ and $N$, its closing side must coincide with the line $MN$, and therefore the pole of the force diagram must lie somewhere on a line through $H$ parallel to $MN$. Let $O'$ be
a point on this line. Then if a new force diagram is drawn with $O'$ as pole, the corresponding equilibrium polygon starting at $M$ will pass through $N$.

134. **Equilibrium polygon through three given points.** Let it be required to pass an equilibrium polygon through three given points, say $M$, $N$, and $L$ (Fig. 123).

As in the preceding article, a trial force diagram is first drawn with any point $O$ as pole, and the corresponding equilibrium polygon constructed, thus determining the reactions $R_1$ and $R_4$ as $AH$ and $HE$ respectively.

Now if the equilibrium polygon is to pass through $N$, the pole of the force diagram must lie somewhere on a line $HK$ drawn through $H$ parallel to $MN$, as explained in the preceding article. The next step, therefore, is to determine the position of the pole on this line $HK$, so that the equilibrium polygon through $M$ and $N$ shall also pass through $L$. This is done by drawing a vertical $LS$ through $L$ and treating the points $M$ and $L$ exactly as $M$ and $N$ were treated. Thus $OABCD$ is the force diagram for this portion of the original figure, and $MA'B'C'S$ is the corresponding equilibrium polygon, the reactions for this partial figure being $AH'$ and $H'D$. If, then, the equilibrium polygon is to pass through $L$, its closing side must be the line $ML$, and consequently the pole of the force diagram must lie on a line $H'K'$ drawn through $H'$ parallel to $ML$. The pole is therefore completely determined as the intersection $O'$ of the lines $HK$ and $H'K'$. If, then, a new force diagram is drawn with $O'$ as pole, the
corresponding equilibrium polygon starting from the point \( M \) will pass through both the points \( L \) and \( N \).

Since there is only one position of the pole \( O' \), but one equilibrium polygon can be drawn through three given points. In other words, an equilibrium polygon is completely determined by three conditions.

135. Application of equilibrium polygon to calculation of stresses. Consider any structure, such as an arch or arched rib, supporting a system of vertical loads, and suppose that the force diagram and equilibrium polygon are drawn as shown in Fig. 124. Then each ray of the force diagram is the resultant of all the forces which precede it, and acts along the segment of the equilibrium polygon parallel to this ray. For instance, \( OC \) is the resultant of all the forces on the left of \( P_s \), and acts along \( C'D' \). Consequently the stresses acting on any section of the structure, say \( mn \), are the same as would result from a single force \( OC \) acting along \( C'D' \).

Let \( \alpha \) denote the angle between the segment \( C'D' \) of the equilibrium polygon and the tangent to the arch at the point \( S \). Then the stresses acting on the section \( mn \) at \( S \) are due to a tangential thrust of amount \( OC \cos \theta \); a shear at right angles to this, of amount \( OC \sin \theta \); and a moment of amount \( OC \cdot d \), where \( d \) is the perpendicular distance of \( C'D' \) from \( S \).

From Fig. 124, it is evident that the horizontal component of any ray of the force diagram is equal to the pole distance \( OH \). Therefore if \( OC \) is resolved into its vertical and horizontal components, the moment of the vertical component about \( S \) is zero, since it passes
through this point; and hence the moment \( OC \cdot d = OH \cdot z \), where \( z \) is the vertical intercept from the equilibrium polygon to the center of moments \( S \). Having determined the moment at any given point, the stresses at this point can be calculated as explained in Article 149.

136. Relation of equilibrium polygon to bending moment diagram. In the preceding article it was proved that the moment acting at any point of a structure is equal to the pole distance of the force diagram multiplied by the vertical intercept on the equilibrium polygon from the center of moments. For a system of vertical loads, however, the pole distance is a constant. Consequently the moment acting on any section is proportional to the vertical intercept on the equilibrium polygon from the center of moments. Therefore, if the equilibrium polygon is drawn to such a scale as to make this factor of proportionality equal to unity, the equilibrium polygon will be identical with the bending moment diagram for the given system of loads.

Problem 160. Compare the bending moment diagrams and equilibrium polygons for the various cases of loading illustrated in Article 52.

II. CONCRETE AND MASONRY ARCHES

137. Definitions and construction of arches. The following discussion of the arch applies only to that form known as the barrel arch. Domed and cloistered arches demand a special treatment which is beyond the scope of this volume.

The various portions of a simple, or barrel, arch, such as shown in projection in Fig. 125, have the following special names.

Soffit: the inner or concave surface of the arch.

Intrados: the curve of intersection (\( ACB \), Fig. 125) of the soffit, with a vertical plane perpendicular to the axis, or length, of the arch.

Extrados: the curve of intersection (\( DEF \), Fig. 125) of a vertical plane with the outer surface of the arch.

Crown: the highest part of the arch.
Haunches: the parts of the arch next to the abutments.

Springing line: the line \( AB \) joining the ends of the intrados.

Rise: the distance from the springing line to the highest point of the intrados.

Spandrel: the space above the extrados. In the case of an arch supporting a roadway, the filling deposited in this space is called the spandrel filling.

Voussoir: any one of the successive stones in the arch ring of a masonry arch.

Keystone: the central voussoir.

In constructing an arch the material is supported while being put in place by a wooden structure called a center, the outer surface of which has the exact form of the soffit of the required arch. The center is constructed by making a number of frames or ribs having the form of the intrados of the required arch, and then placing these ribs at equal intervals along the axis of the arch and covering them with narrow wooden planks, called lagging, running parallel to the axis of the arch. When the arch is completed, or, in case of a concrete arch, when the material has hardened sufficiently to resist the stress due to its weight, the centers are removed, thus leaving the arch self-supporting.

138. Load line. Since the filling above an arch has the same form as the arch itself, it must be partly self-supporting. In designing an arch, however, no advantage is taken of this fact, and it is assumed that any portion of the extrados supports the entire weight of the material vertically above it. The only exception to this is in the construction of tunnel walls, in which case it would be obviously unnecessary as well as impracticable to construct an arch sufficiently strong to support the entire weight of the material above it.

If the filling above an arch is not of the same material as the arch ring, subsequent calculations are greatly simplified by constructing a load line which shall represent at any point the height which a filling of the same material as the arch itself must have in order to produce the same load as that actually resting on the arch. The vertical intercept between the intrados and the load line will then represent the load at any given point of the arch.

In case of a live load the load line will have a different form for each position of the moving load.

Problem 161. A circular arch of 20 ft. span and 6 ft. rise, with an arch ring 3 ft. thick, is composed of concrete weighing 140 lb./ft.\(^3\). Construct the load line
for a roadway three feet above the crown of the arch, with a spandrel filling of earth weighing $100 \text{ lb./ft.}^3$.

Solution. In this case the weight of a cubic foot of the spandrel filling is to the weight of a cubic foot of the arch ring as $100 : 140$. Therefore the load line is obtained by reducing the intercept on each ordinate between the roadway and the extrados in the ratio $140:100$. Thus, in Fig. 126, reducing any ordinate $AB$ in this ratio we obtain the ordinate $BC$, etc. By carrying out this reduction on a sufficient number of ordinates, and joining the points $C$ so found, the load line $DECFG$ is obtained.

139. Linear arch. Suppose that the voussoirs of an arch have slightly curved surfaces so that they can rock on one another, as shown in Fig. 127. The points of contact of successive voussoirs are then called centers of pressure, and the line joining them the line of pressure, or linear arch. It is evident, from the figure, or from a model constructed as above, that with every change of loading the voussoirs change their position more or less, thus altering the form of the linear arch. In a model constructed as above, the linear arch can alter its shape considerably without overthrowing the structure, the only condition necessary to assure stability being that the linear arch shall lie between the intrados and the extrados.*

In a masonry arch the pressure on any joint is ordinarily distributed over the entire surfaces in contact. In this case the center of pressure is the point of application of the resultant joint pressure, and

the linear arch is the broken line joining these centers of pressure. In a concrete arch the linear arch becomes a continuous curve. With each change of loading the same shifting of the linear arch occurs as in the case of the model with curved joints, the only difference being that with flat joints this action is not visible. To assure stability, however, the linear arch must be restricted to lie within the middle third of the arch ring, as will be proved in Article 140.

If we consider a single voussoir of a masonry arch, or a portion of a concrete arch bounded by two plane sections, as shown in Fig. 128, the resultant joint pressures $R$ and $R'$, and the weight $P$ of the block and the material directly above it, form a system of forces in equilibrium. Consequently, if the amount, direction, and point of application of one of these resultant joint pressures are known, the amount, direction, and point of application of the other can be found by constructing a triangle of forces. Therefore, if one resultant joint pressure is completely known in position, amount, and direction, the others can be successively found as above, thus determining the linear arch as an equilibrium polygon for the given system of loads.

Since an equilibrium polygon may be drawn to any given scale, if no one joint pressure is completely known, which is usually the case, there will be, in general, an infinite number of equilibrium polygons corresponding to any given system of loads. The linear arch may, however, be defined as that particular equilibrium polygon which coincides with the pressure line, and the question then arises how to determine the equilibrium polygon so that it shall coincide with the pressure line. This problem will be discussed more fully in Articles 142, 143, and 144.

When the linear arch has been determined, the resultant pressure on a joint having any inclination to the vertical can easily be obtained. Thus, in Fig. 129, let $R$ be the resultant pressure on a
vertical section through $B$, and $R'$ the resultant pressure on the inclined section $AE$ through $B$. Since $R$ is due to the load on the right of the vertical $CF$, and $R'$ to the load on the right of the broken line $DAE$, the difference between them must be due to the load $ABCD$ minus the load $BFE$. Let $P$ denote the difference between these two loads, represented by the shaded portion in Fig. 129. Then, since $R$, $R'$, and $P$ must be in equilibrium, $R'$ is found at once by drawing a force triangle, as shown in the figure.

140. Conditions for stability. A masonry arch may fail in any one of three ways: (1) by sliding of one voussoir upon another; (2) by overturning; (3) by crushing of the material.

These three methods of failure will now be considered in order.

1. The first method of failure is caused by the shearing stress at any joint exceeding the joint friction, or the adhesion of the mortar. This kind of failure can only occur when the angle which the resultant pressure on any joint makes with a normal to the plane of the joint exceeds the angle of repose for the material in question (Article 159). Ordinarily the resultant pressure on any joint is very nearly perpendicular to its plane, and since the angle of repose for masonry is very large, failure by sliding is not likely to occur.

As a criterion for safety against failure of this kind, it may be assumed that when the resultant makes an angle of less than $30^\circ$ with the normal to the joint safety against sliding is assured.

2. In order for an arch to fail by overturning, one or more of the joints must open at one edge, the adjacent blocks rotating about their center of pressure. For this to occur, one edge of the joint must be in tension. Although in a well-laid masonry arch the joints have considerable tensile strength, it is customary to disregard this entirely, and in this case the condition necessary to assure stability against rotation is that every joint shall be subjected to compressive stress only. Assuming, then, a linear distribution of
stress over the joints, the center of pressure is restricted to lie within the middle third of any joint (compare Article 62).

Thus, in Fig. 130 (A), if $ABCD$ represents the distribution of pressure on any joint $AD$, the resultant $R$ must pass through the center of gravity of the trapezoid $ABCD$. Consequently, when the compression at one edge becomes zero, as shown in Fig. 130 (B), the resultant $R$ is applied at a point distant $\frac{b}{3}$ from $A$, and cannot approach any nearer to $A$ without producing tensile stress at $D$. Therefore, the criterion for stability against overturning is that the center of pressure on any joint shall not approach nearer to either edge than $\frac{b}{3}$, where $b$ is the width of the joint; or, in other words, that the linear arch must lie within the middle third of the arch ring.

3. Failure by crushing can only occur when the maximum stress on any joint exceeds the ultimate compressive strength of the material. To guard against this kind of failure, 10 is universally chosen as the factor of safety. Hence, if $u_c$ denotes the ultimate compressive strength of the material, and $p_{\text{max}}$ the maximum unit stress on any joint, the criterion for stability against crushing is

$$p_{\text{max}} < \frac{u_c}{10}.$$  

From Fig. 130 (B), the maximum unit stress is twice the average. Therefore, if $F$ denotes the area of a joint, and $p_a$ the average unit stress on it,

$$p_a = \frac{R}{F} \quad \text{and} \quad p_{\text{max}} = 2p_a.$$

Consequently the criterion for stability against crushing can be expressed in the more convenient form

$$\frac{R}{F} < \frac{u_c}{20}.$$

---

**Fig. 130**
that is to say, the average unit stress on any joint must not exceed one twentieth of the ultimate compressive strength of the material.

The above conditions for stability can be applied equally as well to a concrete arch by considering the stress on any plane section of the arch ring.

141. Maximum compressive stress. Let $R$ denote the resultant pressure on any joint, $b$ the width of the joint, $F'$ its area, and $c$ the distance of the center of pressure from the center of gravity of the joint. Then, under the assumption of a linear distribution of stress, the stress on the joint is due to a uniformly distributed thrust of amount $\frac{R}{F'}$ per unit of area, and a moment $M$ of amount $M = Rc$.

Therefore the unit stress $p$ at any point is given by the formula

$$p = \frac{R}{F'} \pm \frac{Me}{I},$$

where $e$ is the distance of the extreme fiber from the center of gravity, and $I$ is the moment of inertia of the cross section.

For a section of unit length, $F' = b \cdot 1 = b$, $I = \frac{b^4}{12}$, and $e = \frac{b}{2}$.

Therefore, substituting these values, the formula for maximum or minimum stress becomes

$$p_{\text{max}} = \frac{R}{b} \pm \frac{6 Rc}{b^3}. $$

For $e = \frac{b}{6}$ the minimum stress is zero, and if $e > \frac{b}{6}$ it becomes negative, thus restricting the center of pressure to lie within the middle third of the cross section if tensile stress is prohibited (compare Article 62 and Article 140, 2).

Combining this result with that of the preceding article, the maximum stress calculated by the formula

$$p_{\text{max}} = \frac{R}{b} + \frac{6 Rc}{b^3}$$

must not exceed $\frac{u_c}{10}$, where $u_c$ is the ultimate compressive strength of the material.

142. Location of the linear arch: Moseley's theory. In order to obtain a starting point for the construction of the linear arch, it is necessary to know the amount, direction, and point of application
of one joint pressure, as explained in Article 139; or, in general, it is necessary to have given three conditions which the equilibrium polygon must satisfy, such, for instance, as three points through which it is required to pass. Since it is impossible to determine these three unknowns by the principles of mechanics, the theory of the arch has long been a subject of controversy among engineers and mathematicians.

Among the various theories of the arch which have been proposed from time to time, the first and most important of the older theories is called the principle of least resistance. This theory was introduced by the English engineer, Moseley, in 1837, and later became famous on the Continent through a German translation of Moseley’s work by Scheffler.

In building an arch the material is assembled upon a wooden framework called a center; when the arch is complete this center is removed and the arch becomes self-supporting, as explained in Article 137. Now suppose that instead of removing the center suddenly, it is gradually lowered so that the arch becomes self-supporting by degrees. In this case the horizontal pressure or thrust at the crown gradually increases until the center has been completely removed, when it has its least possible value. This hypothesis of least crown thrust consistent with stability is Moseley’s principle of least resistance.

In constructing an equilibrium polygon the horizontal force, or pole distance, is least when the height of the polygon is a maximum. Therefore, in order to apply the principle of least resistance, the equilibrium polygon must pass through the highest point of the extrados at the crown and the lowest points of the intrados at the abutments. Since this would cause tensile stress at both the crown and abutments, the criterion for stability against overturning makes it necessary in applying the theory to move the center and ends of the equilibrium polygon, or linear arch, until it falls within the middle third of the arch ring. There is nothing in the principle of least resistance, however, to warrant this change in the position of the equilibrium polygon, and consequently the theory is inconsistent with its application.

Culmann tried to overcome this objection to Moseley’s theory by considering the compressibility of the mortar between the joints. At the points of greatest pressure the mortar will be compressed more
than elsewhere, and this will cause the pressure line, or linear arch, to move down somewhat, thus taking a position nearer to the middle third than is required by the principle of least resistance, if applied to the arch as a rigid body.

The above brief account of Moseley's principle of least resistance and Culmann's modification of it are given chiefly for their historical interest and the importance formerly attached to them. The modern theory of the arch is based upon the principle of least work, and is therefore rigorously correct from the standpoint of the mathematical theory of elasticity.

143. Application of the principle of least work. Although Hooke's law is not rigorously true for such materials as stone, cement, and concrete, the best approximation to actual results is obtained by assuming that the materials of which the arch is composed conform to Hooke's law, and then basing the theory of the arch on the general theorems of the strength of materials. On this assumption the position of the linear arch can be determined by means of Castigliano's theorem, which states that for stable equilibrium the work of deformation must be a minimum (Articles 78 and 80).

Consider a section of the arch perpendicular to the center line of the arch ring, or, in general, normal to the intrados. Let $F$ denote the area of the section, $R$ the resultant pressure on the section, $c$ the distance of the point of application of $R$ from the center of gravity of the section, and $ds$ an infinitesimal element of the center line. Then the work of deformation will consist of two parts,—that due to the axial thrust $R$, and that due to a moment $M = Rc$. Since the direct stress per unit of area of the section is $\frac{R}{F}$, the unit deformation due to the stress is $\frac{R}{FE}$, where $E$ denotes Young's modulus; and hence the work of deformation due to $R$ is $\frac{1}{2} R \left( \frac{R}{FE} \right)$, or $\frac{R^2}{2FE}$.

From Article 72, Chapter IV, the work of deformation due to the bending moment $M$ is $\frac{M^2}{2EI}$. Therefore the work of deformation $dW$ for a portion of the arch included between two cross sections at a distance $ds$ apart is

$$dW = \frac{R^2}{2FE} ds + \frac{M^2}{2EI} ds.$$
Hence the total work of deformation for the entire arch is

\[ W = \int \frac{R^2}{2EF} ds + \int \frac{M^2}{2EI} ds. \]

Let \( b \) denote the thickness of the arch ring, and consider a section of unit width. Then \( F = b \) and \( I = \frac{b^4}{12} \), and substituting these values in the above equation and assuming that \( E \) is constant throughout the arch,

\[ W = \frac{1}{2E} \int \left( \frac{R^2}{b} + \frac{12M^2}{b^3} \right) ds. \]

In Article 139 it was shown that three conditions are necessary for the determination of the linear arch. Therefore, since the values of \( R \) and \( M \) in the above expression depend upon the position of the linear arch, in order to apply Castigliano’s theorem to the integral, \( R \) and \( M \) must first be expressed in terms of these three unknown quantities, which may be conveniently chosen as the position, amount, and direction of the joint pressure at a certain point.

Having expressed \( R \) and \( M \) in this way, Castigliano’s theorem is applied by differentiating \( W \) partially with respect to each of the three unknowns, and equating these three partial derivatives to zero. In this way three simultaneous equations are obtained which may be solved for the three unknown quantities, thus completely determining the linear arch.

The principle of least work, therefore, permits of a rigorously correct determination of the linear arch. Instead, however, of actually carrying out the process outlined above, Winkler has applied the principle to the derivation of a simple criterion for stability, as explained in the following article.

144. Winkler’s criterion for stability. From the preceding article, the total work of deformation for the whole arch is given by the expression

\[ W = \frac{1}{2E} \int \left( \frac{R^2}{b} + \frac{12M^2}{b^3} \right) ds, \]

in which the integral is to be extended over the entire length of the arch. As the position of the pressure line is altered, the first term in this integral changes but little, whereas the second term undergoes a considerable variation, since \( M = Rc \), where \( c \) is the distance
of the center of pressure from the center of gravity of the section. For a first approximation, therefore, the first term may be disregarded in comparison with the second, and hence the problem of making \( W \) a minimum reduces to that of making the integral \( \int \frac{M^2}{b^3} \, ds \) as small as possible.

To effect a still further reduction, suppose that \( R \) is resolved into vertical and horizontal components so that the vertical component shall pass through the center of gravity \( G \) of the section (Fig. 131), and let \( z \) denote the perpendicular distance of the horizontal component \( P_h \) from \( G \). Then \( M = P_h z \) and the integral \( \int \frac{M^2}{b^3} \, ds \) becomes \( \int \frac{P_h^2 z^2}{b^3} \, ds \), or, since \( P_h \) is constant for all sections, this may be written \( P_h^2 \int \frac{z^2}{b^3} \, ds \).

Ordinarily the thickness of the arch ring varies, being least at the crown and greatest at the abutments. In this case let \( b_c \) denote the thickness of the crown, and suppose that the law of variation in thickness is such that the thickness \( b \) at any other point is given by the expression

\[
\frac{b}{b_c} = \frac{dx}{dz},
\]

where \( dx \) is the horizontal projection of \( ds \). Under this assumption, the expression \( P_h^2 \int \frac{z^2}{b^3} \, ds \) becomes

\[
\frac{P_h^2}{b_c^3} \int z^2 \, dx.
\]

Therefore the problem of making \( W \) a minimum is now reduced to that of making the integral \( \int z^2 \, dx \) as small as possible.

This latter expression, however, consists of only positive terms, and reduces to zero for the center line of the arch. From this it follows that if an equilibrium polygon is drawn for the given system of loads, and then the center line of the arch is so chosen as to coincide with this equilibrium polygon, the true linear arch can differ but little from this center line.
In order for an arch to be stable at least one of the many possible assumptions of the linear arch must be such as to fall within the middle third of the arch ring. Moreover, the elastic deformation of the arch is such as to move the linear arch as near to the center line as the form of the arch permits. Therefore, *if for any given arch it is possible to draw an equilibrium polygon which shall everywhere lie within the middle third of the arch ring, the stability of the arch is assured.*

This criterion for stability is due to Winkler, and was first given by him in 1879.

145. Empirical formulas. The thickness necessary to give an arch at the crown can only be found by assuming a certain thickness and determining whether or not this satisfies all the conditions of stability. The least thickness consistent with stability is such that the average compressive stress does not exceed one twentieth of the ultimate compressive strength of the material. The arch is usually made somewhat thicker than is required by this criterion, however, for the thicker the arch the more easily can the equilibrium polygon be made to lie within the middle third of the arch ring.

The following empirical formulas for thickness at crown represent the best American, English, and French practice respectively, and may be used in making a first assumption as a basis for calculations.

\[ b = \frac{\sqrt{r + \frac{l}{2}}}{4} + 0.2; \quad \text{Trautwine.} \]

\[ b = \sqrt{12r}; \quad \text{Rankine.} \]

\[ b = 1 \frac{1}{12} + \frac{l}{23}; \quad \text{Perronnet.} \]

\[ r = \text{radius of intrados in feet}; \quad d = \text{rise in feet}; \]

\[ l = \text{span in feet}; \quad b = \text{depth at crown in feet}. \]

146. Designing of arches. In designing an arch to support a given loading the equilibrium polygon for the given system of loads should, in accordance with Winkler's criterion, be assumed as the center line of the arch. This, however, is not always possible. For instance, in
the case of an arch intended to support a roadway, the level of which is fixed, the loading depends to a large extent on the form of the arch, and consequently the equilibrium polygon cannot be determined until the form of the arch has been assumed.

In designing arches, therefore, the method usually followed is to assume the form of the intrados of the required arch, and determine its thickness at the crown by an empirical formula, such as those given in the preceding article. Then, having drawn the extrados and load line, the surface between the intrados and the load line is divided into any convenient number of parts by drawing verticals, and the amount and position of the resultant weight of each part for a section one foot wide is calculated. An equilibrium polygon for this system of loads is then passed through the middle point of the arch ring at crown and abutments by the method given in Article 134. If this equilibrium polygon lies within the middle third of the arch ring, the arch is assumed to be stable against overturning.

If the equilibrium polygon through the middle points of the arch ring at crown and abutments does not lie entirely within the middle third of the arch ring, these three points are shifted so as to make it do so if possible. If no choice of the three points will make the equilibrium polygon lie entirely within the middle third of the arch ring, the design must be altered until this has been accomplished.

The next step is to calculate the maximum unit joint pressure by the formula given in Article 141, and apply the criterion for stability against crushing given in Article 140. When these criteria have been satisfied the design is assumed to be safe. If, however, there is a considerable excess of strength, the design may be lightened and the criteria reapplied.

Before the design can be considered complete it must also be shown that the above criteria are satisfied for every form of loading to which the arch is likely to be subjected. In the case of an arch designed to carry a heavy live load, such as that due to several locomotives, it may be necessary to draw a number of load lines corresponding to different positions of the load, and make a corresponding number of determinations of the equilibrium polygon and maximum joint pressure.
The stability of the abutments still remains to be investigated, and finally the bearing power of the soil on which these abutments rest.

**Problem 162.** Design a concrete arch to span a stream 25 ft. in width and support a roadway 15 ft. above the level of the stream, if the spandrel filling is clay weighing 120 lb./ft.\(^3\); the maximum depth of frost is 3\(\frac{1}{2}\) ft. and the bearing power of the soil at this depth is 4 tons/ft.\(^2\) (see Article 158).

**147. Stability of abutments.** To determine the stability of the abutments, the joint pressure at the haunch is combined with the weight of the abutment into a single resultant, say \(R'\). For stability against overturning, the line of action of this resultant must strike within the middle third of the base (Article 140, 2).

Resolving the resultant \(R'\) into a horizontal component \(R_h\) and a vertical component \(R_v\), the maximum pressure on the soil is calculated by substituting this value of \(R_v\) for \(R\) in the formula given in Article 141. To prevent sinking of the abutments, this pressure must not exceed the bearing power of the soil (see Article 158).

For stability against sliding, the shearing stress between the abutment and the soil, due to the horizontal component \(R_h\) of the resultant \(R'\), must be less than the friction between the two; or, more briefly, the angle which \(R'\) makes with the horizontal must be less than the angle of repose (compare Article 164).

**148. Oblique projection of arch.** Suppose that an arch, its load line, and its pressure line are drawn to any given scale, and then the whole figure is projected upon an oblique plane by a system of parallel lines. The projection of the pressure line on this oblique plane will then be the true pressure line for the projected arch and its projected load line.

This principle can often be used to advantage, as, for example, in comparing two arches of equal span but different rise. Its most important application is in giving an accurate construction of the pressure line for arches of long span and small rise. Thus, instead of plotting such an arch to scale, its projection can be plotted; or, in other words, its span can be shortened any convenient amount. A larger unit can then be used in plotting the vertical dimensions than would otherwise be possible, and consequently the pressure line can be drawn to any desired degree of accuracy.

Having constructed the pressure line in this way, the pressure on any joint of the given arch can be found from the pressure on the
corresponding joint of the projected arch by laying off the horizontal and vertical components of the latter to two different scales; in other words, by projecting the pressure back again onto the original arch.

III. Arched Ribs

*149. Stress in arched ribs. The arch is frequently used in metal constructions, especially in such structures as roofs and bridges, in the form of a curved beam composed either of a solid web and flanges or built up like a truss. Such a metal arch is called an arched rib.

The fundamental difference between a concrete or masonry arch and an arched rib is that the latter, being composed of metal, is capable of resisting bending moment. For an arched rib, therefore, it is not essential that the equilibrium polygon shall lie within the boundaries of the arch; it may, in fact, either cross the arch or lie entirely on either side, the only condition for stability being that the arched rib must be sufficiently strong to resist the bending moment thus produced.

*For a brief course the remainder of this chapter may be omitted.
When the equilibrium polygon has been drawn for the given system of loads, the stress at any point of an arched rib can be calculated by the method explained in Article 135. Thus, in Fig. 132 (A), let $AGF$ denote the arched rib, $P_1, P_2$, etc. the given loads, and $ABCDEF$ the corresponding equilibrium polygon. Then the stress on any section $mn$ is due to a force acting in the direction $CD$, of amount equal to the corresponding ray $OC'$ of the force diagram.

Consequently, if the rib is composed of a solid web and flanges, as shown in Fig. 132 (B), the direct stress on the section is equal to the ray $OC'$ of the force diagram, the bending stress on the upper flange is $P_{kz}' \frac{C'}{d}$, the bending stress on the lower flange is $P_{kz} \frac{C'}{d}$, and the shear normal to the rib is $OC'$ sin $\alpha$, where $\alpha$ is the angle between $CD$ and the tangent to the rib at the section.

Similarly, for the trussed rib shown in Fig. 132 (C), by taking moments about $L$ and $S$ the stresses in $RS$ and $LK$ are found to be $P_{x} \frac{z}{d}$ and $P_{y} \frac{z}{d}$, respectively, while the normal component of the stress in $LS$ is $OC$ sin $\alpha$.

Arched ribs are usually constructed in one of three different ways: (1) hinged at the abutments and at the crown; (2) hinged at the abutments and continuous throughout; (3) fixed at the abutments and continuous throughout. The method of constructing the equilibrium polygon differs for each of these three methods of support, and will be treated separately in what follows.

150. Three-hinged arched rib. When a member is free to turn at any point the bending moment at that point is zero, and consequently the equilibrium polygon, or bending moment diagram, passes through the point. For a three-hinged arched rib, therefore, the equilibrium polygon must pass through the centers of the three hinges and is therefore completely determined, as explained in Article 134.

151. Two-hinged arched rib. Consider an arched rib hinged at the ends and continuous between these points. In this case the equilibrium polygon must pass through the centers of both hinges, but since there is no restriction on the vertical scale, this scale may be anything whatever, depending on the choice of the pole in the
force diagram. A third condition is therefore necessary in order to make the problem determinate.

The problem can be solved in various ways, depending on the choice of the third condition. The first solution that will be given is that found by applying the principle of least work, that is, by applying Castigliano's condition that the work of deformation shall be a minimum.

Consider a two-hinged arched rib supporting a system of vertical loads, as shown in Fig. 133. Then the moment at any point \( A \) is equal to the moment of the forces on the left of the section \( mn \) through \( A \), minus the moment of \( P_h \) about \( A \), where \( P_h \) is the unknown horizontal reaction, or pole distance of the force diagram, which is to be determined. Consequently, if \( M \) denotes the moment at \( A \), \( M_p \) the moment of the forces on the left of \( A \), and \( z \) the perpendicular distance of \( P_h \) from \( A \), we have

\[
M = M_p - P_hz.
\]

Since the work of deformation due to the shear and axial load is small, it may be neglected in comparison with that due to the bending moment. Under this assumption the work of deformation is

\[
W = \frac{1}{2} \int \frac{M^2}{EI} ds = \frac{1}{2} \int \left( \frac{M_p - P_hz}{EI} \right)^2 ds,
\]

in which the integral is to be extended over the entire length of the rib. Applying the principle of least work to this expression, the partial derivative of \( W \) with respect to the unknown quantity \( P_h \) must be zero. Hence
\[
\frac{\partial W}{\partial P_h} = - \int \frac{(M_p - P_h z)}{EI} z ds = 0,
\]

or
\[
- \int \frac{M_p z}{EI} ds + P_h \int \frac{z^2}{EI} ds = 0;
\]

whence
\[
P_h = \frac{\int \frac{M_p z}{EI} ds}{\int \frac{z^2}{EI} ds}.
\]

If \( E \) is constant throughout the rib, this reduces to
\[
P_h = \frac{\int \frac{M_p z}{I} ds}{\int \frac{z^2}{I} ds}.
\]

The pole distance \( P_h \) found from this formula is the third condition necessary for the complete determination of the equilibrium polygon.

152. Second method of calculating the pole distance. The value of the pole distance \( P_h \) of the force diagram can also be calculated by assuming that the bending of the rib produces no change in the span. To apply this condition, the change in length which the span would naturally undergo is calculated and equated to zero.

Consider a small portion \( ds \) of the rib. If, for the moment, the rest of the rib is regarded as rigid, the bending of this portion would make the end \( B \) revolve about \( D \) as a center to a position at \( C \) (Fig. 134). Let \( d\beta \) denote the angle between \( DB \) and \( DC \), \( \alpha \) the angle between \( DB \) and a vertical through \( D \), \( z \) the ordinate \( DF \), and \( CE \), or \( \Delta l \), the change in length of the span. Then
\[
BC = DB \cdot d\beta, \quad DB \cos \alpha = z, \quad \text{and} \quad \Delta l = CB \cos \alpha.
\]

Hence
\[
\Delta l = DB \cdot d\beta \cos \alpha = zd\beta.
\]
From Article 66, the angular deformation $d\beta$ is given by the expression

$$d\beta = \frac{M ds}{EI}.$$ 

Consequently

$$\Delta l = zd\beta = \frac{Mz}{EI} ds,$$

and hence the total change in length of the span is

$$l = \int \frac{Mz}{EI} ds.$$

Therefore the condition that the span shall be unchanged in length by the strain is

$$\int \frac{Mz}{EI} ds = 0.$$

The bending moment $M$ in this expression has the same value as in the preceding article, namely, $M = M_p - P_kz$. Inserting this value of $M$ in the above condition, it becomes

$$\int \left(\frac{M_p - P_kz}{EI}\right) z ds = 0,$$

from which, as in the preceding article,

$$P_k = \frac{\int \frac{Mz^2}{I} ds}{\int \frac{z^2}{I} ds}.$$

153. Graphical determination of the linear arch. From the condition that the bending stress shall produce no change in the length of the span, the position of the linear arch may be determined graphically as follows.

In Fig. 135 let $ACF$ represent the center line of the rib, $ADF$ the corresponding equilibrium polygon drawn to any convenient scale, and $ABF$ the linear arch. Then the linear arch can be obtained from the equilibrium polygon by reducing each ordinate of the latter in a certain

* The effects of changes of temperature and also of direct compressive stress in altering the length of the span are neglected, as they are slight in comparison with that due to bending strain.
ratio, say $r$. The problem then is to find this ratio $r$ in which the ordinates to the equilibrium polygon must be reduced to give the linear arch.

The condition that the span is unchanged in length, derived in the preceding article, is

$$\int \frac{Mz}{EI} \, ds = 0,$$

in which $z$ represents the ordinate $CE$ to the rib, and $ds$ an element of the rib. Since the bending moment $M$ is proportional to the vertical intercept between the linear arch and the center line of the rib, this condition may be written

$$\int \frac{BC \cdot z}{EI} \, ds = 0;$$

or, since $E$ may be assumed to be constant and

$$BC = BE - CE = BE - z,$$

this condition becomes

$$\int \frac{(BE - z)z}{I} \, ds = 0,$$

which may be written

$$\int \frac{BE \cdot z}{I} \, ds - \int \frac{z^2}{I} \, ds = 0.$$

If $r$ denotes the ratio in which the ordinates to the equilibrium polygon must be decreased in order to give the linear arch, then

$$r = \frac{BE}{DE},$$

and consequently the condition becomes

$$\int \frac{r \cdot DE \cdot z}{I} \, ds - \int \frac{z^2}{I} \, ds = 0;$$

whence

$$r = \frac{\int \frac{z^2}{I} \, ds}{\int \frac{DE \cdot z}{I} \, ds}.$$

This expression for $r$ can be evaluated graphically by replacing the integrals by summations and calculating the given functions for a
series of vertical sections taken at equal intervals *along the rib*. Thus, since $ds$ in this case is constant,

$$r = \frac{\sum \frac{z^2}{I}}{\sum \frac{DE \cdot z}{I}}$$

in which the functions under the summation signs are to be calculated for each section separately, and their sum taken. After $r$ has been found in this way the linear arch is obtained by decreasing the ordinates of the equilibrium polygon in the ratio $r:1$, and the stress can then be calculated as explained in Article 149.

This method of determining the linear arch is due to Ewing.

**154. Temperature stresses in two-hinged arched rib.** When the temperature of an arched rib changes, the length of the rib also changes, and consequently stresses called *temperature stresses* are produced in the rib (compare Article 19). To calculate the amount of this stress let $L$ denote the coefficient of linear expansion and $T$ the change in temperature in degrees. Then each element of the rib of length $ds$ changes its length by the amount $LTds$, the horizontal projection of which is $LTdx$. Therefore the total change $l$ in the length of the rib is

$$l = \int_0^{2c} LTdx = 2cLT,$$

where $2c$ is the span. From Article 152, the total change in length of the span is given by the expression

$$l = \int_0^l \frac{Mz}{EI} ds.$$

Therefore

$$\int_0^l \frac{Mz}{EI} ds = 2cLT.$$

To simplify this expression assume that the modulus of elasticity $E$ is constant throughout the rib, and that the moment of inertia $I$ increases towards the abutments in the ratio $\frac{ds}{dx}$. Under this assumption $I = I_0 \frac{ds}{dx}$, where $I_0$ denotes the moment of inertia at the crown, and the above equation becomes

$$\frac{1}{EI_0} \int_0^{2c} Mzdx = 2cLT.$$
The only forces which tend to resist the change in length of the rib due to temperature stresses are the horizontal reactions $P_h$ of the abutments. Therefore the external moment at any section of the rib with ordinate $z$ is $M = P_hz$, and substituting this value in the above integral, it becomes

$$\frac{P_h}{EI_0} \int_0^{2c} z^2 dx = 2cLT;$$

whence

$$P_h = \frac{2EI_0cLT}{\int_0^{2c} z^2 dx}.$$

This expression is easily evaluated in any given case, thus determining $P_h$ and consequently the linear arch. The temperature stresses can then be calculated by the methods explained above, and combined with those due to the given loading. For a rise in temperature above that for which the arch was designed, $T$ is positive and the horizontal reactions $P_h$ of the abutments act inwardly; for a fall in temperature $T$ is negative and the reactions $P_h$ act outwardly.

To illustrate what precedes, the above formula will now be applied to a parabolic arched rib, which on account of its simplicity is the form ordinarily assumed in designing. Let $h$ denote the rise of the arch, $2c$ its span, and $x, z$ the coordinates of any point $A$ on the rib (Fig. 136). Then, from the intrinsic property of the parabola, it follows that

$$\frac{h - z}{h} = \frac{(c - x)^2}{c^2};$$

whence

$$z = \frac{hx}{c^2} (2c - x).$$
Substituting this value of \( z \) in the integral \( \int_0^{2e} z^2 dx \) and integrating, we have
\[
\int_0^{2e} z^2 dx = \int_0^{2e} \left[ \frac{hx}{e^z} (2e - x) \right]^2 dx = \frac{16 eh^2}{15}.
\]
Consequently for a parabolic arched rib the horizontal reaction of the abutments due to a change in temperature of \( T \) degrees is
\[
P_h = \frac{2 EILcLT}{16 eh^2} = \frac{15 EILcLT}{8 h^2}.
\]

155. Continuous arched rib fixed at both ends. For a continuous arched rib fixed at both ends the problem of constructing the equilibrium polygon is subject to a threefold indetermination, since none of the three conditions necessary for its determination are given. The theoretical solution of the question by the principle of least work is as follows.

Let the vertical reaction \( R \), the horizontal reaction \( P_h \), and the bending moment \( M_0 \) at the left support be chosen as the three unknown quantities necessary to determine the linear arch. For a system of concentrated loads the moment \( M \) at any section of the rib distant \( x \) from the left support is
\[
M = M_0 + Rx - P_hz - \sum_{i=1}^{x} P(x - d),
\]
in which \( d \) is the distance of any load \( P \) from the left support, and the summation is to be extended over all the loads between the left support and the point under consideration. Similarly, for a uniform load of amount \( w \) per unit of length,
\[
M = M_0 + Rx - P_hz - \frac{wx^2}{2}.
\]

Now, from Article 72, the work of deformation \( W \) is given by the expression
\[
W = \frac{1}{2} \int \frac{M^2}{EI} ds,
\]
in which \( M \) has the value given by one or the other of the above expressions, depending on whether the loading is concentrated or uniform. To apply Castigliano's theorem to this expression it is
necessary to find the partial derivatives of \( W \) with respect to \( M_0 \), \( R_1 \), and \( P_h \) respectively, and equate these derivatives to zero. The three conditions obtained in this way are

\[
\frac{\partial W}{\partial M_0} = \int \frac{M}{EI} \cdot \frac{\partial M}{\partial M_0} \, ds = \int \frac{M}{EI} \, ds = 0,
\]

\[
\frac{\partial W}{\partial R_1} = \int \frac{M}{EI} \cdot \frac{\partial M}{\partial R_1} \, ds = \int \frac{M}{EI} \, ds = 0,
\]

\[
\frac{\partial W}{\partial P_h} = \int \frac{M}{EI} \cdot \frac{\partial M}{\partial P_h} \, ds = - \int \frac{M}{EI} \, ds = 0,
\]

since from either of the above expressions for \( M \) we have \( \frac{\partial M}{\partial M_0} = 1 \), \( \frac{\partial M}{\partial R_1} = x \), and \( \frac{\partial M}{\partial P_h} = -z \). Inserting in these three conditions the value of \( M \) for the given form of loading, three simultaneous equations are obtained which may be solved for the three unknown quantities \( R_1 \), \( P_h \), and \( M_0 \).

Equations (103) can also be obtained by assuming as our three conditions that the horizontal and vertical deflections of the supports are zero, and that the direction of the rib at the ends remains unchanged. The method of obtaining equations (103) from these assumptions is simply an extension of that given in Article 152 for the two-hinged arched rib.

156. Graphical determination of the linear arch for continuous arched rib. The simplest method of applying equations (103) to the determination of the linear arch is by means of a graphical treatment similar to that given in Article 153.

Consider first the case of symmetrical loading. Then if \( M_0 \) denotes the bending moment at either abutment, the linear arch has the same
form as for a rib with two hinges, except that its base is shoved down a distance \( M_0 \) below the springing line of the rib. Therefore in this case the linear arch is completely determined by the two quantities \( M_0 \) and \( r \), the third condition being supplied by the symmetry of the figure.

In Fig. 137 let \( ACF \) represent the center line of the rib, \( A'B'F' \) the linear arch, and \( ADF \) the equilibrium polygon for the given system of loads. Since the bending moment \( M \) at any point of the rib is the vertical intercept \( BC \) between the linear arch and the center line of the rib, we have

\[
M = BC = BE - CE' - EE',
\]

or, since \( BE = r \cdot DE' \),

\[
M = r \cdot DE' - z - M_0.
\]

Substituting this value of \( M \) in the first and third of equations (103), they become

\[
\int \frac{rDE'}{EI} ds - \int \frac{z}{EI} ds - \int \frac{M_0}{EI} ds = 0,
\]

and

\[
\int \frac{rDE'^2 ds}{EI} - \int \frac{z^2}{EI} ds - \int \frac{M_0 z}{EI} ds = 0.
\]

If the expressions under these integral signs are evaluated for a number of vertical sections taken at equal distances along the rib, and the results are summed, we obtain the two conditions

\[
r \sum \frac{DE'}{I} - \sum \frac{z}{I} - M_0 \sum \frac{1}{I} = 0,
\]

and

\[
r \sum \frac{DE' \cdot z}{I} - \sum \frac{z^2}{I} - M_0 \sum \frac{z}{I} = 0,
\]

from which \( r \) and \( M_0 \) can easily be determined. The linear arch is then constructed by starting from a point at a distance \( M_0 \) below the left support, and decreasing the ordinates to the equilibrium polygon in the ratio \( r : 1 \).

If the loading is unsymmetrical, the moments at the ends of the rib are not equal. Let \( M_1 \) and \( M_2 \) denote the moments at the left and right ends respectively (Fig. 138). As before, the moment \( M \) at any point of the rib is the vertical intercept \( BC \) between the linear arch \( A'B'F' \) and the center line of the rib \( ACF \). Consequently

\[
M = BC = BE - CE' - EE'.
\]
In this case, however, the distance $EE'$ is not constant from $A$ to $F$, but varies as the ordinates to a triangle, being equal to $M_1$ at $A$ and to $M_2$ at $F$. Hence, for a point at a distance $x$ from $A$,

$$(EE')_x = M_1 - \frac{x}{2c} (M_1 - M_2),$$

where $2c$ is the length of the span. Also $BE = r \cdot DE$, and $CE' = z$. Therefore

$$M = r \cdot DE - z - M_1 + \frac{x}{2c} (M_1 - M_2).$$

Let this value of $M$ be inserted in equations (103). Then, if the expressions under the integral signs are evaluated for a number of vertical sections taken at equal distances along the center line of the rib, and their sums taken, the integrations in equations (103) can be replaced by summations giving the three conditions

$$r \sum \frac{DE}{I} - \sum \frac{z}{I} - M_1 \sum \frac{1}{I} + \frac{M_1 - M_2}{2c} \sum \frac{x}{I} = 0,$$

$$r \sum \frac{DE \cdot x}{I} - \sum \frac{zx}{I} - M_1 \sum \frac{x}{I} + \frac{M_1 - M_2}{2c} \sum \frac{x^2}{I} = 0,$$

$$r \sum \frac{DE' \cdot z}{I} - \sum \frac{z^2}{I} - M_1 \sum \frac{z}{I} + \frac{M_1 - M_2}{2c} \sum \frac{zx}{I} = 0.$$
Solving these three equations simultaneously for $M_1$, $M_2$, and $r$, the linear arch is constructed by laying off $M_1$ and $M_2$ from $A$ and $F$ respectively, and then reducing the ordinates to the equilibrium polygon in the ratio $r:1$, and laying them off from the line $A'F'$.

The stresses in the rib can then be calculated by the methods previously given (Article 149).

157. Temperature stresses in continuous arched rib. Using the notation of Article 154, the change in the length of the span due to a change in temperature of $T$ degrees is

$$l = 2cLT.$$

Therefore, for temperature stresses equations (103) become

$$\int \frac{M}{EI} ds = 0, \quad \int \frac{Mx}{EI} ds = 0, \quad \int \frac{Mz}{EI} ds = -2cLT.$$

By hypothesis, the only external forces acting on the rib are the reactions and moments at the abutments due to the temperature stresses. Consequently, if $R$ denotes the vertical reaction, $P_h$ the horizontal reaction, and $M_1$ the moment at the left abutment, the moment $M$ at any other point of the rib is

$$M = M_1 + Rx - P_hz.$$

If, then, this value of $M$ is inserted in the above integrals and the resulting equations solved simultaneously for $M_1$, $R$, and $P_h$, the linear arch is thereby determined.
CHAPTER XI

FOUNDATIONS AND RETAINING WALLS*

158. Bearing power of soils. Since the character of a foundation is dependent upon the nature of the soil on which it is to rest, it is necessary in designing a foundation to know with a reasonable degree of accuracy the maximum load which the soil can sustain per unit of area without appreciable settlement; or, in other words, what is known as the bearing power of the soil.†

Ordinarily the results of previous experience are relied upon to give an approximate value of the bearing power of any given soil, and stability is assured by the adoption of a large factor of safety. For structures of unusual importance, however, or when the nature of the soil is uncertain, the results of previous experience are usually insufficient to assure stability, and special tests are necessary for the determination of the bearing power of the soil in question. Among notable structures for which such special tests have been made may be mentioned the State Capitol at Albany, N.Y.; the Congressional Library at Washington, D.C.; the suspension bridges at Brooklyn, N.Y., and at Cincinnati, Ohio; the Washington Monument; the Tower Bridge, London, etc.

By averaging the results of a large number of such tests, reliable information is furnished as to the bearing power of soils in general. The most commonly accepted of such average values are those given by Professor I. O. Baker in his Treatise on Masonry Construction, and are as shown in the table on the following page. Other values in common use are also quoted for comparison, and may be accepted as representative of modern practice.

* For a more detailed treatment of foundations and retaining walls the following special treatises may be consulted. Baker, Treatise on Masonry Construction; Howe, Retaining Walls for Earth; Fowler, Ordinary Foundations; Merriman, Walls and Dams; Patton, Ordinary Foundations.

† The bearing power of soils is analogous to what is called the crushing strength in the case of more rigid materials, such as stone and brick.
As an approximate working rule Trautwine recommends from 2 to 3 tons/ft.² as a safe load for compact gravel, sand, or loam, and from 4 to 6 tons/ft.² if a few inches of settlement may be allowed.*

The building laws of Greater New York may also be regarded as competent authority, and specify the following values.

<table>
<thead>
<tr>
<th>Material</th>
<th>Bearing Power tons/ft.²</th>
</tr>
</thead>
<tbody>
<tr>
<td>Firm, coarse sand, stiff gravel, or hard clay</td>
<td>4</td>
</tr>
<tr>
<td>Loam, clay, or fine sand, firm and dry</td>
<td>3</td>
</tr>
<tr>
<td>Ordinary clay and sand together, wet and springy</td>
<td>2</td>
</tr>
<tr>
<td>Soft clay</td>
<td>1</td>
</tr>
</tbody>
</table>

As a supplement to the above, these laws also specify that when foundations are carried down through earth by piers of stone or brick, or by concrete in caissons, the loads on same shall not exceed 15 tons/ft.² when carried down to rock, or 10 tons/ft.² when carried down to firm gravel or hard clay.

In order to obviate too large or expensive a foundation, it is often desirable to increase the bearing power of the soil. This may be accomplished in various ways.

Since, in general, soils are more condensed at greater depths, increasing the depth usually increases the bearing power of the soil.

*Engineer’s Pocket-Book, 1902, p. 583.
In the case of wet or moist soils the same effect is obtained by drainage, as indicated in the tables on the preceding page.

A more marked increase in the bearing power may be obtained by excavating the soil and replacing it by a layer of moist sand; or by driving short piles and then either removing them and filling the hole immediately with moist sand, or else leaving the piles in the earth and covering them with a platform of timber or concrete.

When none of these methods will suffice, the soil must be excavated until a subsoil with an adequate bearing power is reached.

159. Angle of repose and coefficient of friction. When a mass of granular material, such as sand, gravel, or loose earth, is poured upon a level surface, the sides of the pile will assume a definite slope, called the natural slope. This maximum angle which the sides of the pile can be made to assume with the horizontal is called the angle of repose, and is a constant for any given material. Since the size of this angle is dependent upon the amount of friction between the particles of the material, it may be taken as a measure of the friction, or vice versa.

The laws of friction as determined by experiment are that the force of friction is independent of the areas in contact, is dependent on the nature of the material, and is directly proportional to the normal pressure between the surfaces in contact. Let \( P_F \) denote the force of friction and \( P_N \) the normal pressure. Then the above laws may be expressed by the formula

\[
P_F = k P_N,
\]

where \( k \) is the constant of proportionality, and is called the coefficient of friction.

In Fig. 139 let \( DE \) represent the natural slope and \( \omega \) the angle of repose, and consider a particle of the material of weight \( P \) at any point \( A \) in the natural slope. Let \( P \) be resolved into two components
$P_F$ and $P_N$, respectively parallel and perpendicular to $DE$. Then $P_F = P_N \tan \omega$, and comparing this with the relation $P_F = kP_N$,

$$k = \tan \omega;$$

that is to say, the coefficient of friction is equal to the tangent of the angle of repose.

The following table gives the numerical values of the angles of repose and coefficients of friction for various materials, and also the weight in pounds of one cubic foot of each material.*

160. Bearing power of piles. The custom of driving piles into the soil to increase its bearing power is of very ancient origin, and is still frequently used because of its cheapness and efficiency. Until quite

* See Fanning, *Treatise on Hydraulic and Water Supply Engineering*, 15th ed., 1902, p. 345; Trautwine, *Engineer’s Pocket-Book*, 1902, pp. 407–411; *Smithsonian Physical Tables*, 1906, Table 95; also the results compiled by Rankine from experiments by General Morin and others, *ibid.*, Table 140.
recently wood was the only material used for piles, and they were either driven by hand with sledges, or by means of a block, usually of metal, which was raised between two upright guides and allowed to fall on the head of the pile. The latter form of pile driver is still in frequent use for driving wooden piles, and is called the drop-hammer pile driver.

In 1839 Nasmyth invented the steam pile driver, which consists essentially of a steam cylinder supported vertically above the head of the pile by two uprights fastened to a cap which rests on the pile. The hammer in this case is a weight attached to the piston rod, and delivers a blow on the head of the pile at each stroke of the piston. The uprights which support the cylinder also serve as guides for the hammer, which varies in weight from 550 lb. to 4800 lb. This form of pile driver owes its efficiency to the rapidity with which the blows can be given, the number being from sixty to eighty per minute, thus preventing the soil from recovering its equilibrium between strokes, and greatly decreasing its resistance to penetration.

In modern engineering practice cast-iron and concrete piles are rapidly coming into use, and as neither of these materials is capable of standing repeated blows, piles of this kind are usually driven by means of an hydraulic jet. The jet is attached to the point of the pile, thus constantly excavating the soil in front of the pile as it descends, and enabling it to sink into place with little or no assistance other than its own weight.

The rational formulas in ordinary use for determining the bearing power of piles are based upon the assumption that the pile is driven by a drop-hammer pile driver, and express its bearing power in terms of the amount of penetration at the last blow. Since the bearing power of a pile is due in part to the friction of the earth on the sides of the pile, as well as to the resistance of the subsoil to penetration, and also since part of the energy of the hammer is absorbed by the friction of the guides, in compressing the head of the pile, in compressing the hammer, in overcoming the inertia of the pile, etc., a rigorous formula is too complicated to be of much practical value, although there are a number of elaborate discussions of the bearing power of piles which take all of these elements into consideration, notably the
theories of Rankine and Weisbach.* However, as several of the elements entering into the discussion are attended with considerable uncertainty, it is customary in practice to use either an empirical formula or the simple approximate formula deduced below, adopting a factor of safety large enough to cover the assumptions made.

Let \( P \) denote the weight of the hammer in pounds, \( h \) the height of the fall in inches, \( R \) the average resistance of the soil to penetration during the last blow in pounds, and \( d \) the penetration of the pile, due to the last blow, in inches. Then, assuming that all the work done by the hammer is expended in overcoming the resistance of the earth at the point of the pile, we have

\[ Ph = Rd. \]

With a factor of safety of 6, the approximate formula for safe load on the pile becomes

\[ R = \frac{Ph}{6d}. \]

(104)

As the head of a timber pile becomes " broomed " by repeated blows, and this greatly decreases the efficiency of the blow by absorbing the kinetic energy of the hammer, the head should be sawed off to a solid surface before making a test blow for determining the bearing power of the pile.

For a drop-hammer pile driver the empirical formula in most common use is

\[ R = \frac{2Ph}{d + 1}, \]

(105)

the notation being the same as above, and the factor of safety being 6. For a steam pile driver this formula becomes

\[ R = \frac{2Ph}{d + 0.1}, \]

(106)

where \( Ph \) represents the kinetic energy of the hammer.

The above empirical formula, (105) or (106), is commonly known as Wellington's formula, or the Engineering News formula, and has been incorporated in the building laws of Greater New York.

The only means of determining the bearing power of a pile driven by an hydraulic jet, is to observe the maximum load it can support without appreciable settlement.

* See Baker, Treatise on Masonry Construction, chap. xi.
FOUNDATIONS AND RETAINING WALLS  201

Problem 163. A one-ton hammer falls 15 ft. on the head of a pile, and the settlement is observed to be .1 in. Calculate the safe load for the pile by formulas (104) and (105) and compare the results.

Problem 164. Under what conditions will the approximate rational formula (104) and the Engineering News formula (105) give substantially the same results?

Solution. If the values of \( R \) obtained from these two formulas were equal, then
\[
\frac{Ph}{6d} = \frac{2Ph}{d + 1}; \quad \text{whence } d = \frac{1}{15} \text{ in.}
\]
For other values of \( d \) the rational formula gives the greater value of the bearing power when \( d < \frac{1}{15} \text{ in.} \), and the empirical formula gives the greater value when \( d > \frac{1}{15} \text{ in.} \). From this it follows that the empirical formula is only applicable when the settlement at the last blow is small.

161. Ordinary foundations. Although the foundation of a structure is necessarily the first part to be constructed, it is the last part to be designed, for the weight of the structure determines the nature of the foundation, and this cannot be calculated until the structure has assumed definite proportions.

The load which a structure is designed to carry consists primarily of three parts.

1. The dead load, due to the weight of the structure and the permanent fixtures, such as plumbing and heating apparatus, elevators, water tanks, machinery, etc.

2. The live load, which depends on the use to which the structure is to be put, and which may vary from 20 lb./ft.\(^2\) to 400 lb./ft.\(^2\)

3. The wind load, due to the overturning action of the wind upon the side of the structure. These three parts of the total load must be calculated separately and then combined so as to give the maximum resultant. The area of the foundation is then found at once by dividing this maximum load by the safe bearing power of the soil.

The chief concern in designing a foundation, however, is not that its settlement shall be zero, but that it shall be uniform throughout. For if one part of a foundation settles more than another, it is evident that cracks are bound to occur which will seriously weaken the structure and may even destroy its usefulness altogether. Since uniformity of settlement implies uniformity of pressure on the soil, the condition which determines the stability of a foundation and its superstructure is simply uniformity of pressure on the soil.

The effect of violating this condition is frequently seen, the most common instance being that of ordinary dwelling houses in which several openings, say a door and a number of windows, occur one
above another. It is evident in this case that if the foundation is of
the same width throughout, the centers of pressure will fall outside
the centers of resistance, which will tend to throw the top of the wall
outward on either side, and so result in cracks between the openings
(Fig. 140). The remedy for this is either to narrow the foundation,
or omit it altogether under the openings, or else extend it beyond
the ends of the wall, the length of this extension being of such amount
that the centers of pressure will fall inside, or at least coincide with, the
centers of resistance.

When a foundation extends beyond the ends of a wall the projec-
tion is called the footing. To dimen-
sion the footing it may be regarded
as a simple cantilever, and its thickness calculated by the ordinary
theory of beams. Thus let \( h \) denote
the thickness of the footing in
inches for a concrete foundation,
or the thickness of the bottom foot-
ing course in inches for a masonry
foundation, \( b \) the width of the foot-
ing in inches, \( u \) the ultimate strength of the material in lb./in.\(^2\), and
\( P \) the load in tons/ft.\(^2\). Then, since 1 ton/ft.\(^2\) = 13.9 lb./in.\(^2\), the
moment at the face of the wall is

\[
M = (13.9 \; Pbx) \cdot \frac{x}{2};
\]

or, since \( I = \frac{bh^3}{12} \) and \( u = \frac{M}{I} \), we have \( u = \frac{41.7 \; x^2 P}{h^2} \); whence

\[
h = 6.45 \; x \sqrt{\frac{P}{u}}, \text{ approximately.}
\]

Problem 165. Find the thickness of the bottom footing course for a masonry
foundation if the load is 1 ton/ft.\(^2\), the factor of safety is 10, the footing is to
extend 18 in. beyond the face of the wall, and is composed of limestone for which
\( u = 15,000 \) lb./in.\(^2\).
162. Column footings. In the modern construction of tall buildings the design frequently provides that the entire weight of the building and its contents shall be carried by a steel framework of columns and girders. This “skeleton type” of tall-building construction, as it is called, necessitates a new type of foundation, since each column load must be calculated separately and transmitted to the soil by a footing of sufficient size to give the necessary amount of bearing area.

If the columns reach solid rock, the footing may consist simply of a base plate of such form as to give the column a solid bearing and afford sufficient anchorage to prevent the footing from lateral movement.

For compressible soils the column is usually supported by a cast-iron base plate resting on a footing consisting of two or more layers of steel rails or I-beams, the whole resting on a concrete base, as shown in Fig. 141.
What has been said in the preceding article in regard to the calculation of the loads carried by the foundation also applies to the calculation of column loads, and the method of designing a column footing is essentially the same as for a masonry footing, explained above. Thus let \( P \) denote the total column load in tons, \( c \) the length of one side of the base plate in inches, and \( l \) the length in inches of the beams supporting it (Fig. 141). Then, if the base plate is assumed to be stiff enough to carry the load on its perimeter, the maximum moment \( M \) will occur at one edge of the base plate. Since the reaction on one side of the base plate is \( 2000 \frac{P(l-c)}{2l} \), the amount of this moment is

\[
M = \frac{2000 P(l-c)}{2l} \frac{l-c}{4} = \frac{250 P(l-c)^2}{l} \text{ in. lb.}
\]

Consequently, if \( n \) is the number of beams supporting the base plate, the maximum moment for one beam is

\[
M_1 = \frac{250 P(l-c)^2}{n l} \text{ in. lb.}
\]

If the base plate is assumed to be only stiff enough to distribute the load uniformly, the maximum moment will occur at the center of the beams, and its value will be (cf. Article 52 (E))

\[
M = \frac{2000 P\left(l-\frac{c}{2}\right)}{4} = 250 P(2l-c) \text{ in. lb.}
\]

In this case the maximum moment for one beam is

\[
M_1 = \frac{250 P(2l-c)}{n} \text{ in. lb.}
\]

Now let \( p \) denote the allowable fiber stress per square inch, \( I \) the moment of inertia of a cross section of one beam, and \( e \) half the depth of the beam. Then the moment of resistance of one beam is

\[
M = \frac{pI}{e}
\]

For foundation work \( p \) is usually taken to be 20,000 lb./in.\(^2\). Substituting this value, the moment of resistance becomes

\[
M = 20,000 \frac{I}{e} = 20,000 S,
\]
where $S$ denotes the section modulus. Equating the moment of resistance to the external bending moment and solving the resulting equation for $S$, we have in the first case

$$S = \frac{P(l - c)^2}{80ln},$$

and in the second case

$$S = \frac{P(2l - c)}{80n}.$$

In designing a column footing the column load $P$ is first calculated, and the area of the footing determined by dividing the column load by the safe bearing power of the soil. The size of base plate and number of beams supporting it are next assumed, and the section modulus calculated by one of the above formulas. The size of beam to be used is then determined by choosing from the tables a beam whose section modulus agrees most closely with the calculated value of $S$.

**Problem 166.** Design the footing for a column supporting a load of 400 tons, and resting on a base plate 4 ft. square, so that the pressure on the foundation bed shall not exceed 3 tons/ft.$^2$.

**163. Maximum earth pressure against retaining walls.** A wall of concrete or masonry built to sustain a bank of earth, or other loose material, is called a retaining wall.

In Chapter X it was shown that in order to determine the stability of an arch three conditions were necessary, which might conveniently be chosen as the direction, amount, and point of application of the resultant pressure on any cross section of the arch ring. The same necessity arises in the discussion of retaining walls, namely, that three conditions are necessary for the complete solution of the problem, and a number of theories have been advanced, notably those of Coulomb, Weyrauch, and Rankine, based on different assumptions as to these conditions.

All theories, however, agree upon two of these assumptions, namely, (1) that the pressure against the wall is due to a wedge of earth, or, in other words, that the surface along which the earth tends to slide against the wall is a plane; and (2) that the point of application of the resultant earth pressure is one third of the height of the wall from the bottom. Neither of these assumptions is rigorously correct, for the first is equivalent to neglecting the cohesion of the earth, and
the second assumes that the earth pressure against the wall is the same as if the earth was a liquid. However, the uncertainty attending the exact degree of homogeneity of the materials under consideration probably does not warrant any greater precision in these first two assumptions.

The third assumption relates to the direction of the maximum pressure, and is the point on which the various theories differ. Thus Coulomb and Weyrauch assume that the pressure is normal to the back of the wall; Rankine assumes that it makes an angle with the back of the wall equal to the angle of repose of the material; while other authorities assume values intermediate between these two.

In the present discussion the first two conditions mentioned above will be retained, and the third condition will be replaced by the assumption that the resultant earth pressure makes an unknown angle $\zeta$ with a normal to the back of the wall. The assumptions are, then:

1. The surface of rupture is a plane.
2. The point of application of the resultant pressure is one third of the height of the wall from the bottom.
3. The resultant pressure is inclined at an angle \( \zeta \) to a normal to the back of the wall.

From the result of the theory based on these assumptions, the values of the resultant earth pressure given by Coulomb, Weyrauch, Rankine, and others will then be deduced as special cases by giving different values to \( \zeta \).

In Fig. 142 let \( AB \) represent the back of the wall, \( BD \) the surface of the ground, \( AD \) the natural slope, and \( AC \) any line included between \( AB \) and \( AD \). Also let \( P' \) denote the resultant pressure due to the wedge \( BAC \), \( P_1 \) the weight of this wedge, \( OR \) its reaction against the plane \( AC \), \( \xi \) the angle between \( P' \) and a normal to the back of the wall, \( \omega \) the angle of repose of the earth, \( \alpha \) the angle between the back of the wall and the horizontal, \( \beta \) the angle between the surface of the ground and the horizontal, and \( x \) the angle between \( AC \) and the horizontal.

Then in the triangle \( TOS \), by the law of sines,

\[
P' = P_1 \frac{\sin OTS}{\sin OST};
\]

or, since \( TOR = x - \omega \) and \( TOS = 180^\circ - \alpha - \xi \), we have \( OST = \alpha + \xi - x + \omega \), and, consequently,

\[
P' = P_1 \frac{\sin (x - \omega)}{\sin (\alpha + \xi + \omega - x)}.
\]

To find an expression for \( P_1 \), let \( w \) denote the weight of a unit volume of the material, say the weight of one cubic foot. Then for a section of unit length in the direction of the wall

\[
P_1 = w (\text{area } ABC) = \frac{w}{2} AB \cdot AC \sin BAC;
\]

or, if \( h \) denotes the height of the wall, \( AB = \frac{h}{\sin \alpha} \), \( BAC = \alpha - x \), and \( AC = AB \frac{\sin (\alpha - \beta)}{\sin (x - \beta)} \); whence

\[
P_1 = \frac{wh^2 \sin (\alpha - \beta) \sin (\alpha - x)}{2 \sin^2 \alpha \sin (x - \beta)},
\]

and, consequently,

\[
P' = \frac{wh^2 \sin (\alpha - \beta) \sin (\alpha - x) \sin (x - \omega)}{2 \sin^2 \alpha \sin (x - \beta) \sin (\alpha + \xi + \omega - x)}.
\]
The problem now consists in finding the value of the variable angle \( x \) for which \( P' \) is a maximum, which may be expressed symbolically by the conditions

\[
\frac{dP'}{dx} = 0 \quad \text{and} \quad \frac{d^2P'}{dx^2} < 0.
\]

In order to reduce the expression for \( P' \) to a form more suitable for differentiation, we make use of the following identity.

\[
\cot(a - x) - \cot(a - \omega) = \frac{\cos(a - x)}{\sin(a - x)} - \frac{\cos(a - \omega)}{\sin(a - \omega)} = \frac{\cos(a - x)\sin(a - \omega) - \cos(a - \omega)\sin(a - x)}{\sin(a - x)\sin(a - \omega)} = \frac{\sin(x - \omega)}{\sin(a - x)\sin(a - \omega)};
\]

whence

\[
\sin(x - \omega) = \sin(a - x)\sin(a - \omega)[\cot(a - x) - \cot(a - \omega)].
\]

Similarly,

\[
\sin(x - \beta) = \sin(a - x)\sin(a - \beta)[\cot(a - x) - \cot(a - \beta)],
\]

and

\[
\sin(a + \omega + \zeta - x) = \sin(a - x)\sin(\omega + \zeta)[\cot(a - x) - \cot(\omega + \zeta)].
\]

Substituting these values in the expression for \( P' \), the latter becomes

\[
P' = \frac{wh^2\sin(a - \omega)}{2\sin^2a\sin(\omega + \zeta)} \cdot \frac{\cot(a - x) - \cot(a - \omega)}{[\cot(a - x) - \cot(a - \beta)][\cot(a - x) + \cot(\omega + \zeta)]}.
\]

Now the terms in this expression which contain the variable \( x \) are all of the same form, namely, \( \cot(a - x) \). This term may therefore be replaced by a new variable \( y \), and the remaining terms by letters denoting constants. Thus let

\[
\cot(a - x) = y, \quad \frac{wh^2\sin(a - \omega)}{2\sin^2a\sin(\omega + \zeta)} = A,
\]

\[
\cot(a - \omega) = B, \quad \cot(a - \beta) = C, \quad \cot(\omega + \zeta) = D.
\]

Then

\[
P' = A \frac{y - B}{(y - C)(y + D)}.
\]

Equating to zero the first derivative of \( P' \) with respect to \( y \), we have

\[
\frac{dP'}{dy} = A \frac{(y - C)(y + D) - (y - B)(y - C) - (y - B)(y + D)}{(y - C)^2(y + D)^2} = 0;
\]

whence the condition for a maximum is

\[
y = B + \sqrt{(B - C)(B + D)}.
\]
Substituting this value of \( y \) in the expression for \( P' \), the latter becomes

\[
P_{\text{max}}' = \frac{A}{(\sqrt{B-C} + \sqrt{B+D})^2} = \frac{A}{(B+D) \left( 1 + \sqrt{\frac{B-C}{B+D}} \right)^2};
\]

or, replacing \( A, B, C, D \) by their values,

\[
P_{\text{max}}' = \frac{wh^2 \sin^2 (a - \omega)}{2 \sin^2 \alpha \sin (\alpha + \xi)} \cdot \frac{1}{\left( 1 + \sqrt{\frac{\sin (\omega - \beta) \sin (\omega + \xi)}{\sin (\alpha - \beta) \sin (\alpha + \xi)}} \right)^2},
\]

which is the general formula for the maximum inclined earth pressure against retaining walls.*

The various standard theories as to the maximum earth pressure may now be obtained as special cases of the above general formula by making the following assumptions.

1. **Weyrauch’s formula.** Assume that the pressure is normal to the back of the wall. Then \( \xi = 0 \), and formula (107) becomes

\[
P_{\text{max}}' = \frac{wh^2 \sin^2 (a - \omega)}{2 \sin^2 \alpha \left( 1 + \sqrt{\frac{\sin (\omega - \beta) \sin \omega}{\sin (\alpha - \beta) \sin \alpha}} \right)^2}.
\]

2. **Rankine’s formula.** Assume that the angle of repose of earth on masonry is equal to the angle of repose of earth on earth. Then \( \xi = \omega \), and formula (107) becomes

\[
P_{\text{max}}' = \frac{wh^2 \sin^2 (a - \omega)}{2 \sin^2 \alpha \sin (\alpha + \omega)} \cdot \frac{1}{\left( 1 + \sqrt{\frac{\sin (\omega - \beta) \sin 2 \omega}{\sin (\alpha - \beta) \sin (\alpha + \omega)}} \right)^2}.
\]

3. **Poncelet’s formula.** In Rankine’s formula assume that the earth surface is horizontal and the back of the wall is vertical. Then \( \beta = 0^\circ \) and \( \alpha = 90^\circ \), and the preceding formula becomes

\[
P_{\text{max}}' = \frac{wh^2 \cos \omega}{2 (1 + \sqrt{2 \sin \omega})^2}.
\]

4. **Coulomb’s formula.**† Assume, as in 3, that the earth surface is horizontal and the back of the wall vertical, and make the further

† Deduced in 1773.
assumption that the pressure is normal to the back of the wall. Then
\( \beta = 0, \alpha = 90^\circ, \xi = 0, \) and formula (107) becomes
\[
P_{\text{max}}' = \frac{wh^2}{2} \tan^2 \left( 45^\circ - \frac{1}{2} \omega \right).
\]

5. **Rankine’s formula for vertical wall.** Assume that the back of the
wall is vertical and that the line of action of the resultant earth
pressure is parallel to the surface of the earth. Then \( \alpha = 90^\circ, \xi = 90^\circ + \beta - \alpha, \) and formula (107) becomes
\[
P_{\text{max}}' = \frac{wh^2 \cos^2 \omega}{2 \cos \beta \left( 1 + \sqrt{\frac{\sin (\omega + \beta) \sin (\omega - \beta)}{\cos \beta}} \right)^2}.
\]

6. **Maximum normal pressure.** Assume that \( \beta \) has its maximum
value, which will be when \( \beta = \omega. \) Then Weyrauch’s
formula becomes
\[
P_{\text{max}}' = \frac{wh^2 \sin^2 (\alpha - \omega)}{2 \sin^2 \alpha},
\]
which is the greatest normal thrust that can be caused by
a sloping bank.

**Problem 167.** A wall 20 ft.
high is inclined at an angle of 85\(^\circ\)
to the horizontal and supports a
backing of clayey gravel the sur-
face of which makes an angle of
20\(^\circ\) with the horizontal. Compute
the maximum pressure against the
back of the wall by Weyrauch’s and
Rankine’s formulas, and compare
the results.

**Problem 168.** By the use of
Poncelet’s formula compute the
maximum pressure in the preceding
problem if the back of the wall is
vertical and the surface of the ground is horizontal.

**Problem 169.** What is the greatest normal pressure that can be caused by a
bank of loose sand against a vertical wall 18 ft. high?

164. **Stability of retaining walls.** The conditions for the stability
of a retaining wall are the same as those given in Article 147 for the
FOUNDATIONS AND RETAINING WALLS

stability of abutments, namely, that the wall must be secure against sliding on its base and against overturning.

Let $P_2$ denote the weight of the wall, $P'$ the resultant earth pressure, and $R$ the resultant of $P_2$ and $P'$ (Fig. 143). Then, if $R$ is resolved into two components $R_F$ and $R_N$, respectively parallel and perpendicular to the base of the wall, the condition for stability against sliding is that $R_F$ shall be less than the friction on the base, or, symbolically,

$$R_F < kR_N.$$

Let $g$ denote the factor of safety. Then this condition may be written

$$R_F = \frac{kR_N}{g}.$$  \hspace{1cm} (108)

To find the values of $R_F$ and $R_N$, let $P'$ and $P_2$ be resolved into components parallel to $R_F$ and $R_N$ respectively. Then, in the notation of the preceding article,

$$R_F = P' \sin (\alpha + \theta + \zeta) - P_2 \sin \theta,$$

and

$$R_N = P_2 \cos \theta - P' \cos (\alpha + \theta + \zeta).$$

Substituting these values of $R_F$ and $R_N$ in equation (108) and solving the resulting expression for $g$,

$$g = \frac{k[P_2 \cos \theta - P' \cos (\alpha + \theta + \zeta)]}{P' \sin (\alpha + \theta + \zeta) - P_2 \sin \theta}.$$  \hspace{1cm} (109)

If the base of the wall is horizontal, $\theta = 0$ and equation (109) becomes

$$g = \frac{k[P_2 - P' \cos (\alpha + \zeta)]}{P' \sin (\alpha + \zeta)}.$$  \hspace{1cm} (110)

For security against sliding the factor of safety should not be less than 3; consequently, the criterion for stability against sliding may be stated as

$$g \geq 3,$$

where the value of $g$ is calculated from equation (109) or (110).

In applying this criterion it should be noted that the value of $\zeta$ must first be assumed (Article 163; $0 \leq \zeta \leq \omega$).

The following table gives average values of the angle of repose and coefficient of friction of masonry on various substances.*

</table>

In order for a wall to fail by overturning, it must either rotate about the outer edge of the base or, in the case of a masonry wall, open at one of the joints. The cause of failure in both cases is the same, namely, that the stress on the base or joint is partly tensile. Consequently, the criterion for stability against overturning is that the resultant $R$ must strike within the middle third of the base or joint, as the case may be (cf. Articles 62, 140, 2, and 147).

This criterion can best be applied graphically. Thus having assumed a value for the angle $\xi$, the resultant earth pressure $P'$ is calculated from the formula in Article 163, corresponding to this assumption of $\xi$, and combined with the weight of the wall into a single resultant $R$. If this resultant does not strike within the middle third of the base, or within the middle third of all the joints in the case of a masonry wall, the design must be altered until the criterion is satisfied.

165. Thickness of retaining walls. In designing a retaining wall economy of material is secured by making the base of such thickness that the resultant $R$, obtained by combining the weight of the wall $P_2$ with the maximum earth pressure $P'$, shall fall at the outer edge of the middle third. However, theoretical formulas for determining the least thickness consistent with this condition are too complicated to be of practical value, and for this reason the design is usually based on an empirical formula.

In railroad practice Trautwine recommends that for vertical walls of rectangular cross section, supporting loose sand, gravel, or earth
level with the top, the thickness $b$ of the base of the wall in terms of its total height $h$ should be as follows:

For wall of cut stone or large ranged rubble in mortar,

$$b = 0.35 h.$$  

For wall of good common scabbled mortar rubble, or brick,

$$b = 0.40 h.$$  

For wall of well scabbled dry rubble,

$$b = 0.50 h.$$  

These empirical rules may be regarded as representative of the best American practice, and may be used to give a first approximation in making a tentative design.

By inclining the wall backward the angle between the earth thrust $P'$ and the wall is decreased, and consequently the resultant $R$ is made to approach more nearly the center of the base. This allows the thickness of the base to be decreased and thus lessens the amount of material in the wall, although it slightly increases its depth. However, there is a restriction upon the amount of inclination which is permissible, for the inclination also has the effect of increasing the tendency to slide on the base or joints. In practice these considerations are balanced by inclining the back of the wall at a small angle, say $5^\circ$ or $10^\circ$, to the vertical (i.e. $\alpha = 80^\circ$ or $85^\circ$), and at the same time cutting the footing into steps perpendicular to the line of action of the resultant $R$, thus securing economy of material without sacrificing stability.

The thickness of the top of the wall is determined by the necessity of providing for the lateral pressure of the earth, due to the action of frost. Since the action of frost is greatest near the top of the wall where the material is most exposed, it is likely to push the top over if the wall is made only thick enough to resist the pressure due to the weight of the earth. This consideration, therefore, limits the least thickness of the wall at the top to about two feet for masonry, or somewhat less than this amount for concrete, since the latter has no joints and therefore offers a greater moment of resistance.

* Engineer's Pocket-Book, 1902, p. 603.

† Masonry composed of rough, undressed stones is called rubble; scabbled rubble has the roughest irregularities knocked off with a hammer.
From the above, it follows that for an economical design the cross section of a wall should be trapezoidal, the thickness of the base being determined by the consideration of stability against overturning, and the thickness of the top by the maximum action of frost.

The inclination of either face of a wall to the horizontal is usually expressed by giving the ratio of the horizontal projection of this face to its vertical projection. This ratio is called the batter, and is given in inches of horizontal projection per foot of height. For example, if a wall makes an angle of $80^\circ$ with the horizontal, it is said to be "battered 2 to 1," since the ratio of its horizontal projection to its vertical projection is equal to $\cot \alpha$, and in the present case

$$\cot \alpha = \cot 80^\circ = 0.1673 = \frac{2}{12},$$
approximate.

**Problem 170.** Design a concrete retaining wall to support a bank of loose earth 25 ft. high, the back of the wall to be inclined backward at a batter of $1\frac{1}{2}$ to 1.
STRENGTH OF MATERIALS

Part II

PHYSICAL PROPERTIES OF MATERIALS
PART II

PHYSICAL PROPERTIES OF MATERIALS

CHAPTER XII

IRON AND STEEL

166. Introductory. A study of the properties of materials used in engineering construction involves a study of the machines used for making the tests and the method of conducting these tests. From the time of Galileo, in 1600 A.D., tests have been made to determine the strength of materials, but only during the past fifty years has any very great advance been made. The rapid development of the past half century has been due to the notable increase in the construction of large buildings, bridges, etc.; for where engineers were formerly content to use material without being tested, the importance of modern constructions demands that the physical properties of the materials used shall be determined for each large contract.

The early testing machine consisted of little more than an ordinary scalebeam with the test piece attached to one end and the load applied at the other. These were used for making tension tests, and machines equally as simple were used for compression and flexure tests. Fig. 144 shows a type of these machines which was used by Kirkaldy about 1860. The specimen to be tested was held in the jaws $g$ while the lever $F$ was in the position of the dotted lines (Fig. 144). A load $N$ was then applied to the end of the lever and gradually increased until the specimen was ruptured.

Testing machines have been much improved during the past twenty or thirty years in the United States by Riehlé Bros. and Olsen & Co.,
both of Philadelphia, Pennsylvania. The machines as now constructed for ordinary testing purposes consist of a platform scales with the usual means of measuring loads, and a screw press operated by an outside source for applying the loads. Fig. 145 is a machine of 100,000 lb. capacity, built by Olsen & Co., and may be taken as a type. The four upright pieces $A$ with the base $B$ upon which they rest form the platform of the scales. This platform rests upon knife-edges $C$ attached to a system of levers $D$ which terminate finally in a graduated lever $E$ (the scalebeam) provided with a movable poise. Each lever is supported by knife-edges resting upon hardened steel plates. The screw press in this case is seen in the

![Fig. 144](image)

four screws $F$ with their movable crosshead $G$. The upper crosshead $H$ is attached to the four upright pieces and is a part of the scale platform.

**167. Tension tests.** If a piece is to be tested in tension, one end is attached to the upper crosshead and the other end to the lower. The turning of the screws, due to the driving mechanism on the other side of the machine, causes the lower crosshead to move downward, thus bringing pressure to bear on the upper crosshead. From here it is transmitted to the base and thence to the levers, and is measured by movement of the poise on the graduated scalebeam. Machines of 20,000 lb., 30,000 lb., 50,000 lb., 100,000 lb., 200,000 lb., and 300,000 lb. capacity are manufactured, as well as a great many machines for making special tension tests. In the larger testing machines the upper head is usually adjustable so as to accommodate specimens of various lengths, but in the smaller machines the upper head is fixed.
The tensile strength in pounds per square inch is computed by dividing the load read from the scalebeam by the area of cross section of the test specimen (see Article 20). Expressed as a formula,

\[
\text{Tensile strength in lb./in.}^2 = \frac{\text{load from scalebeam}}{\text{area of cross section}}.
\]

168. Compression tests. To make compression tests the piece is placed on a small block resting on the platform, and the lower crosshead, provided with a similar block, is brought down upon it. The further lowering of the crosshead compresses the specimen. The pressure comes on the platform through the crossbeam that rests upon it, and is transmitted to the scalebeam, where it is measured.

The compressive strength in lb./in.\(^2\) is computed by dividing the load in pounds as read on the scalebeam by the area of cross section of the test specimen, as in finding the tensile strength.

169. Flexure tests. Beams are tested in flexure by mounting the specimen on a crossbeam provided with knife-edges and applying the load from above by means of a knife-edge attached to the under side of the moving head. The beam is tested by lowering the moving head as in the compression tests.

The fiber stress in the outer fiber of the beam is computed in this case from the formula (see Article 52),

\[
p = \frac{Ple}{4I},
\]

where \(e\) is the distance from the neutral axis to the outer fiber, \(I\) is the moment of inertia with reference to the neutral axis, \(P\) is the load in pounds as read from the scalebeam, \(l\) is the length of the span in inches, and \(p\) is the fiber stress in lb./in.\(^2\).

The maximum deflection for the concentrated central load is computed by the formula (see Article 66),

\[
D = \frac{Pl^3}{48EI},
\]

where \(D\) is the deflection at the center, \(E\) the modulus of elasticity (see Article 8), and \(P, l,\) and \(I\) have the same meaning as above.
In case the beam is loaded at the third points, uniformly, eccentrically, or otherwise, the corresponding expressions are used for fiber stress and deflection (see Articles 52, 66).

170. Method of holding tension specimens. To make a tension test of a material a special test piece is usually provided. This test piece has the same composition as the rest of the material, but has a special form, being larger at the ends than in the central portion (see Article 20). Fig. 146 illustrates a test piece made from a carbon steel bar turned down in the central portion.* The machines are provided with serrated wedges for holding the large ends of the test piece, and as the load is applied these serrations sink into the specimen, thus holding it firmly.

The behavior of the specimen in tension is studied by noting the behavior of the reduced portion, which should be far enough from the ends so that the local stress caused by the wedges will have no effect upon it.

Flat pieces, such as pieces of boiler plate, are left as they come from the rolls on two sides, and the edges are machined to get the reduced cross section, as shown in Fig. 147. The lower specimen, of cast iron, is made with rounded corners to eliminate shrinkage stresses. Rolled material is often tested without being turned down. Special holders and clamps are usually provided for holding tension specimens of timber.

171. Behavior of iron and steel in tension. Wrought iron and mild steel when tested in tension conform to Hooke’s law up to the elastic limit, a point which is usually well defined in these materials. They then suffer a rapid yielding, with little increase of load, reaching a point where the piece elongates very much for no increase of load. This point is known as the yield point. It is indicated by the scaling of the oxide from the specimen that has not been machined, and by the dropping of the beam of the testing machine, if it has been kept balanced up to this point. Beyond this point stress increases much

* Dimensions for standard test specimens of different materials are given in Article 195.
more slowly than deformation, until finally rupture is about to occur, at which point the load attains its maximum value, called the **ultimate load**. If the stress be continued, the piece begins to **neck** and breaks at a load somewhat less than the maximum (see Article 7). This necking is due to the fact that the metal under great strain becomes plastic and flows. Brittle materials, such as cast iron and hard steel, show very little, if any, necking. In computing the fiber stress at the maximum load the original cross section is used.

In commercial tests the load at the yield point (commercial elastic limit) and the maximum load are noted; also the percentage of elongation and the percentage of reduction of cross section. The percentage of elongation is the increase in length divided by the original length multiplied by 100. This percentage varies with the original length taken (see Article 20), and therefore is usually computed for an original length of eight inches. The percentage of reduction of cross section is the decrease in area of the cross section divided by the original area of the cross section multiplied by 100. In some commercial laboratories provision is made for making as many as sixty tests per hour on one machine.

**172. Effect of overstrain on wrought iron and mild steel.** If wrought iron and mild steel are strained just beyond the elastic limit in tension or compression, then released and tested again in the same direction, it has been found that this second test shows that the elastic limit is higher than at first, and almost as high as the load in the first test. Repeated overstrain of this kind, with subsequent annealing, makes it possible to raise the elastic limit considerably above what it was originally. When further strained the metal loses its elasticity and takes on a permanent **set**; that is to say, it does not return to its original length when the stress is removed. The elastic properties, however, can be restored by annealing (see Article 18). Overstrain in either tension or compression destroys almost entirely the elasticity of the material for strain of the opposite kind; for instance, a piece of mild steel overstrained in tension has its elastic properties in compression almost entirely destroyed, and vice versa. Overstraining in torsion produces much the same effect as overstraining in tension or compression.
173. **Relative strength of large and small test pieces.** It has been found by Tetmajer * and others that the values obtained in testing small test pieces taken from different parts of a steel girder or I-beam are higher than those obtained in testing the girder itself. The average of a series of tests of small test pieces gave an elastic limit of 49,000 lb./in.² and a maximum strength of 62,000 lb./in.². Tests on the complete girders themselves gave an elastic limit of 33,500 lb./in.² and a maximum strength of 54,500 lb./in.². The same has been found true for the elastic limit of wrought-iron girders, but in this case the maximum strength is greater in the girder than in the small test piece.

174. **Strength of iron and steel at high temperatures.** From a series of tests made at Cornell University,† it was found that wrought iron having a tensile strength of 30,000 lb./in.² at ordinary temperatures increased in strength with increase of temperature up to 475° F., and then decreased as the temperature was further raised. Machinery steel of 60,000 lb./in.² maximum strength gave at 475° F. a maximum strength of 111,500 lb./in.². Tool steel having a strength of 114,000 lb./in.² at ordinary temperatures gave 145,000 lb./in.² maximum strength at 350° F.

Professor C. Bach also reports an elaborate series of tests on the strength of steel at high temperatures.‡ At ordinary temperatures one bar had a maximum strength of 54,000 lb./in.², an elongation in 8 in. of 26.3 per cent, and a contraction of area of 46.9 per cent. Up to a temperature of 572° F. the strength increased by about 7000 lb./in.², and from this point fell, approximately in proportion to the temperature, to 26,200 lb./in.² at 1022° F. The ultimate elongation decreased to 7.7 per cent at 392° F., and then increased to 39.5 per cent at 1022° F. The contraction of area fell until 392° F. was reached, and did not rise until about 572° F.

While the tensile strength is increased for a moderately high temperature, the elastic limit is lowered in proportion to the increase of temperature, being diminished about 4 per cent for each increase of 100° F.

175. **Character and appearance of the fracture.** The kind and quality of the metal are usually indicated by the character of the

---

fractured portion of the test piece. Two points are to be noted in this connection: the geometrical form and the appearance of the fractured material. Under the first we may have, as in tensile tests of hard steel, a straight fracture where the material breaks squarely off in a plane at right angles to the axis of the test piece; or, as in tensile tests of mild steel and high-grade wrought iron, a fracture which is cup-shaped, half-cup, etc. The appearance of the material for the cup-shaped fracture may be described as dull granular in the bottom of the cup and silky around the edge; or, in the case of wrought iron, as fibrous in the bottom of the cup and silky around the edge. A cast-iron fracture appears crystalline, the crystals being fine, coarse, or medium.

In reporting a test the character and appearance of the fracture should always be given. It should also be noted whether or not any longitudinal seams occur, or whether the fracture shows the material to be homogeneous and free from blowholes and foreign matter. If the specimen has not been properly placed in the machine, so that there is a bending moment, the fracture will indicate this. The axis of the test piece should always coincide with the axis of the machine.

176. Measurement of extension, compression, and deflection. The extension in a tension specimen of iron or steel up to the elastic limit is so slight that very accurate measurements must be made to determine the elongations. Instruments for making such measurements are known as extensometers, and are usually made to read to .0001 of an inch. Fig. 148 shows a type of such instrument known as the Yale-Richlé extensometer. The method of using the instrument is to mark off an 8-in. gauge length on the test piece and fasten the extensometer to it by inserting the screws in the extreme punch marks of the gauge length. The backpiece is then removed and a battery with a bell in circuit is attached; the instrument is then ready for use. As the piece elongates the elongations are measured by turning the micrometer screw until it touches the armature, when the circuit is closed and the bell rings.

The instrument is used only a little past the elastic limit (the limit of proportionality of stress to deformation), and about twenty elongations for corresponding loads are taken below the elastic limit. The instrument is then removed and the test continued to failure, the maximum load being noted. From the data obtained in making
the test, the strain diagram is drawn by using unit loads as ordinates and relative elongations as abscissas. From this curve the elastic limit, modulus of elasticity (Young's modulus), and modulus of elastic resilience may be determined.

The **elastic limit** is found by noting the point on the strain diagram where it ceases to be a straight line.

The **modulus of elasticity** is determined by dividing the stress by the deformation for any stress below the elastic limit.

The **modulus of elastic resilience** is defined as the amount of work required to deform a cubic inch of the material to its elastic limit. It is therefore represented by the area under the strain curve up to the elastic limit, or, expressed as a formula,

\[
\text{Mod. elastic resilience} = \frac{(\text{stress at elastic limit})^2}{2 \text{ modulus of elasticity}}.
\]

If in plotting the strain diagram the ordinates represent the stress expressed in lb./in.\(^2\) and the abscissas represent the corresponding unit elongations, the area under the curve up to the elastic limit multiplied by the scale value in inch-pounds of each unit area gives the modulus of elastic resilience in inch-pounds.

The **modulus of total resilience** is defined as the amount of work required to deform a cubic inch of the material to rupture. It is therefore represented by the area under the whole curve multiplied by the scale value of a unit area, that is, the number of inch-pounds per unit area.

In case the stresses are plotted in pounds and the corresponding deformations in inches, the above method gives the work done on the whole volume of the specimen included in the gauge length. To obtain the modulus for such cases it is necessary, in addition to the above, to divide by the volume of that portion of the specimen over which the deformations were measured.

Compression is measured by means of a **compressometer**, by methods similar to those used in making tension tests. The strain diagram in this case is a **stress-compression** curve.
Fig. 148. — Extensometer

Fig. 150. — Torsion Testing Machine
For measuring deflections in transverse tests various methods are used. A simple instrument for this purpose is shown in Fig. 149. This instrument is placed under the beam and the deflections measured to .001 of an inch. The strain diagram for flexure is thus a *load-deflection* curve.

**Problem 171.** A rod of nickel steel .854 in. in diameter, and with a gauged length of 8 in., when tested in tension gave the data tabulated below. From this data draw the strain diagram and locate the elastic limit; also compute the modulus of elasticity and the modulus of elastic resilience.

**177. Torsion tests.** The determination of the resistance of a material to shear or torsion is usually made by means of a machine designed to read twisting moment in inch-pounds on the scalebeam. The Riehlé machine shown in Fig. 150 may be taken as a type of torsion machines.

In making the test one end of the specimen is attached to the twisting head of the machine and the other end to the stationary head, which is connected by a system of levers to a scalebeam reading inch-pounds of moment. The machine shown in Fig. 150 has the stationary head suspended by stirrups; thus leaving it free to move slightly when the specimen shortens in twisting. The older types of torsion machine are not made to accommodate themselves in this way to the shortening of the test piece.

The angular distortion of the test bar is measured by an instrument called a *tortometer*. This consists of two arms attached to the bar at the extreme points of the part that is being tested. One of these arms carries a scale bent into the arc of a circle of which the arm is
the radius, and having its plane at right angles to the axis of the bar; the other arm carries a pointer so arranged as to move over the scale when the bar is twisted. The arc of the scale is called the troptometer arc and the arm supporting it the troptometer arm. The angular distortion at the center of the bar for the given gauge length is then obtained by dividing the reading on the troptometer arc by the length of the troptometer arm plus the radius of the specimen, or, expressed as a formula,

\[
\text{Angle } \theta \text{ (in radians)} = \frac{\text{reading on troptometer arc}}{\text{troptometer arm} + \text{radius of specimen}},
\]

where \( \theta \) is the angle of twist (see Article 92).

**Problem 172.** A steel rod with a gauged length of 10 in. and .85 in. in diameter, when tested in torsion, gave the data tabulated below. Draw the strain diagram, plotting the stress in lb./in.\(^2\) on the outer fiber as ordinates, and the corresponding angle of twist \( \theta \) as abscissas. Also locate the elastic limit, compute the modulus of elasticity of shear, and the modulus of elastic resilience.

**178. Form of torsion test specimen.** Specimens for torsion tests are made cylindrical, and usually long enough to get a gauged length of 10 in. The cylindrical form has been adopted because its cross sections remain plane during torsion, whereas in other forms a cross section which is plane before torsion is deformed into a warped surface by the strain, and therefore does not give a simple shearing stress (see Article 98). The torsion test is used to determine the shearing strength of materials, that is, the resistance offered by the material to one cross section slipping over another (see Article 67).
When torsion tests are made, the moment in in. lb. is read from the machine, and the shearing stress in the outer fiber in lb./in.² is computed from the formula,

\[ q = \frac{(Pa)r}{I_p} \]

where \( Pa \) is the twisting moment read from the machine, \( r \) the radius of the test piece, and \( I_p \) the polar moment of inertia of the cross section.*

The modulus of elasticity in shear is computed from the relation,

\[ G = \frac{(Pa)l}{\theta I_p} \]

where \( Pa \) and \( I_p \) are defined as above, \( l \) is the gauged length in inches, and \( \theta \) is the angle of twist in radians.

The test piece is held in position by a set of adjustable jaws similar to those used in ordinary pipe wrenches. The gauged length should be taken far enough from the ends so that the local stress due to the jaws may not influence the results.

179. Torsion as a test of shear. Although the torsion test is used to determine the shearing strength of materials, it is not an accurate test, since the shearing stress is a maximum on the outer elements, and zero at the center. For this reason the inner material tends to reënforce the outer, thus giving a higher shearing strength than would otherwise be obtained. A more perfect torsion test would be one made upon a hollow tube of the material, for in this case the inner reënforcing core would not be present. However, the difficulty of obtaining suitable hollow tubes for test pieces makes their use impracticable for ordinary tests.

A further objection to the torsion test as a test of shearing strength lies in the fact that there is considerable tension in the outer elements of the test piece during the test. Any element of the cylindrical test piece which is a straight line before the strain becomes a helix during the test. Since the length of the helix is greater than that of the original element, a tensile stress is thus produced in the outer fibers. In fact, in testing wrought iron in torsion the outer fibers often fail in tension along the helix. The slight shortening

* For a cylinder, \( I_p = \frac{\pi r^4}{2} \).
of the whole specimen, due to the twisting, is corrected in part by the swinging head of the machine shown in Fig. 150.

180. Shearing tests. To determine the shearing strength of timber along the grain and the resistance of iron and steel to the pulling out of rivets, many special tests are used. By means of a special piece of apparatus, the force required to push off, along the grain, a projecting piece from a test piece of timber is easily measured on the ordinary tension-compression machine. The intensity of shearing stress is computed by dividing the load by the area of the block pushed off.

Tests are also made on wrought-iron plates to determine the force required to pull out a rivet through the metal, both in the direction of the fiber and perpendicular to it. A series of such tests may be found in the Watertown Arsenal Report for 1882. Many tests have also been made to determine the shearing strength of rivets.

181. Impact tests. In actual service many materials are subjected to shock or impact (see Article 73). This is especially true of all railway structural material, such as rails, axles, springs, couplers, bolsters, wheels, etc., which must be designed to withstand considerable shock. Two special machines have been designed to test materials in impact. The first, called the drop testing machine, is operated by allowing a given weight (hammer) to drop a given distance upon a test piece mounted on an anvil under the hammer. The other form of machine is operated by allowing a heavy pendulum to strike the specimen when placed in the center of its swing. In either case the amount of the energy of the blow absorbed by the specimen is desired.

The results obtained from impact tests can only be comparative in any case, since a part of the energy of the blow must be absorbed by the parts of the machine itself. This is seen in the drop testing machine in the absorption of energy by the anvil and hammer.

Since the results of such tests cannot be absolute, it is highly necessary that they should be standardized by making tests on the same anvil with the same hammer. The Master Car Builders Association has taken a step toward such standardization by building an impact testing machine for testing materials used by them. This machine has been established at Purdue University. Its maximum blow is given by a hammer having a weight of 1640 lb., and dropping 50 ft.
The use of this machine should do much to standardize specifications for railway material.*

Tests in impact compression, impact tension, and impact flexure are also made, but on account of the uncertainty as to the amount of energy absorbed by the test specimen many engineers do not favor such tests. Many of these objections, however, might be removed by proper standardization.

Some recent investigations seem to indicate that the impact test shows very little that cannot be determined by static tests.

182. Cold bending tests. Cold bending tests are tests of the ductility of metals, and are designed to show the effect on the metal of being bent in various ways while cold. Such material as rivet steel and Bessemer steel bridge pieces are bent double over a pin of specified radius, and the result noted. In making these tests the angle at which the first crack occurs and the angle at which rupture occurs are read.

Few machines for making cold bending tests have been made. The tests are usually made by bending the specimen over the edge of a vise, or some such simple device, according to specifications. The tests have never been standardized, but their importance is obvious, since the conditions of actual service are thus applied to the specimen.

183. Cast iron. Pig iron is a combination of iron with small percentages of carbon, silicon, sulphur, phosphorus, and manganese, obtained from the blast furnace. The carbon probably comes from the fuel used in reducing the ore; the other impurities come either from the ore or from the flux. The product is graded, according to chemical composition, into forge pig and foundry pig. Foundry pig is remelted in a cupola furnace and made into castings of various kinds; forge pig is used in making wrought iron.

Cast iron is a very brittle material, weak in tension and strong in compression. Its great usefulness in engineering structures comes from the fact that it may be readily molded into any desired form; it is, however, being replaced by the various steel products. The carbon, silicon, and other impurities contained in the iron affect its physical properties.

Carbon occurs as combined carbon or as graphitic carbon. Combined carbon makes the metal hard, brittle, white, weak in tension, and strong in compression, whereas graphitic carbon makes the iron soft, gray, and weak in both tension and compression. Graphitic carbon occurs in the metal as a foreign substance, which probably accounts for its weakening effect. Silicon in cast iron up to 0.5 per cent increases its compressive strength. The tensile strength is increased up to 2 per cent. Manganese as it usually occurs is not injurious below 1 per cent. When more is present the shrinkage, hardness, and brittleness are rapidly increased. Phosphorus makes the iron weaker and less stiff, becoming a serious impurity when it occurs in quantities above 1.5 per cent. Sulphur causes whiteness, brittleness, hardness, and greater shrinkage, and is, in general, a very objectionable impurity.

Cast iron has an average tensile strength of 22,500 lb./in.², the range being from 13,000 lb./in.² to 35,000 lb./in.². Its compressive
Strain Diagram
Tension Test of Cast Iron

Fig. 151
strength varies from 50,000 lb./in.\(^2\) to 150,000 lb./in.\(^2\), a good average being about 95,000 lb./in.\(^2\).

The metal is so imperfectly elastic that Hooke's law does not strictly hold for any range of stress, however small. The modulus of elasticity in tension varies from 15,000,000 to 20,000,000 lb./in.\(^2\), and in shear from 5,000,000 to 7,000,000 lb./in.\(^2\). On page 232 is given a table of the tensile strength of various samples of cast iron of different chemical compositions.

184. Strain diagram for cast iron. The strain diagram of cast iron in tension, shown in Fig. 151, illustrates clearly the fact that the metal is very imperfectly elastic. No part of the diagram is a straight line, and no elastic limit is shown by the curve. The maximum load in this case was 34,750 lb./in.\(^2\). The curve was drawn from data given in the Watertown Arsenal Report, 1895. From the results of four hundred and fifty tests of cast iron in tension, compression, and cross-bending, Kirkaldy found the average compressive strength to be 121,000 lb./in.\(^2\), the tensile strength 25,000 lb./in.\(^2\), and the cross-bending modulus (see Article 65) 38,000 lb./in.\(^2\).

Fig. 152 shows a strain diagram of cast iron in compression. Like the tension diagram, this shows no well-defined elastic limit and no constant modulus of elasticity. The maximum compressive strength in this case was 50,000 lb./in.\(^2\).

When tested in compression as a short block, cast iron has a characteristic fracture, shearing along a plane making an angle of about 30° with the vertical. This differs by 15° from the theoretical angle (45°) of maximum stress for such cases.

185. Cast iron in flexure. The most extended series of tests ever made on cast iron in flexure was made by J. W. Keep on bars \(\frac{1}{2}\) in. square and 12 in. long. From these tests, the average strength was found to be 450 lb., giving a modulus of rupture of 64,800 lb./in.\(^2\). A good average for the modulus of rupture for ordinary commercial cast iron would be between 36,000 lb./in.\(^2\) and 42,000 lb./in.\(^2\).

186. Cast iron in shear. The strength of cast iron in shear varies from 13,000 lb./in.\(^2\) to 25,000 lb./in.\(^2\). Tests are made in the ordinary torsion machine. The fracture in this case is the characteristic fracture of brittle materials in torsion; that is, instead of shearing off in a plane at right angles to the axis of the test piece, as is the case with
STRAIN DIAGRAM
COMPRESSION TEST OF CAST IRON

Fig. 152
ductile materials, the fracture extends down one side for some distance. The material fails by the outer fiber failing first in tension. A similar fracture can be seen by twisting a stick of chalk or other brittle material with the fingers until fracture occurs.

187. Cast-iron columns. Some tests have been made upon full-sized cast-iron columns both at the Watertown Arsenal and by the Phoenix Iron Company of Phoenixville, Pennsylvania. The results of these tests show that the total strength of these columns is much less than the compressive strength of the metal would lead one to expect. This was probably due to the presence of blowholes or other imperfections in the column, such as are likely to occur when large pieces are cast. The ultimate strength of the Watertown columns varied from 21,000 lb./in.\(^2\) to 40,000 lb./in.\(^2\).

The following table gives the result of a compression test of a cast-iron column made by the Watertown Arsenal, the ultimate strength in this case being 33,340 lb./in.\(^2\).

**Problem 173.** The data in the preceding table were obtained from a round, hollow, cast-iron column 120 in. in length, 3.05 in. in external diameter, and 1.97 in. in internal diameter. Draw the load-compression and load-deflection
curves for this case, and determine whether or not an elastic limit is indicated. Also compute the strength of the column by Rankine's formula and Johnson's straight-line formula, and compare the results with those obtained from the test.

188. Malleable castings. The castings with combined carbon are hard and brittle. These are heated with some oxide, so that the carbon near the surface is burned out, leaving the outer surface tough and strong, like wrought iron. The interior of the casting is somewhat annealed, but the finished product consists of a hard interior portion with a ductile outer portion. This structure insures strength both statically and as regards impact.

189. Specifications for cast iron.* The following specifications are for special hard cast iron (close-grained). They are taken from the J. I. Case Threshing Machine Company's specifications, and may be considered as typical.

**Chemical Composition**

*Silicon* must be between 1.20 and 1.60 per cent. (Below 1.20 the metal will be too hard to machine; above 1.60 it is likely to be porous unless much scrap is used.)

*Sulphur* must not exceed 0.095 per cent, and any casting showing on analysis 0.115 per cent or more of sulphur will cause the rejection of the entire mixture. (Above 0.115 per cent sulphur produces much shrinkage, shortness, and "brittle hard" iron.)

*Phosphorus* should be kept below .70 per cent unless specified for special thin castings. (High phosphorus gives castings brittle under impact.)

*Manganese* should not be above .70 per cent except in special chilled work.

**Physical Tests**

Transverse breaking strength. The test bars should be 1 in. square and 13\(\frac{3}{4}\) in. long, and should be tested with a load of 2400 lb. applied at the center of a 12-in. span.

* These specifications, as well as all others quoted, are given so that the student may get an idea of the composition and properties required of commercial cast iron or other material. Specifications issued by different companies vary, and those issued by the same company are frequently changed on account of the requirements of service.
Deflection should not be less than 0.08 in.

Tensile strength must not be less than 22,000 lb./in.².

The following specifications for cast iron are suggested by J. W. Keep as being representative of modern practice.*

Transverse test bars were cast 1 in. square and 12 in. long, and were tested with a central load. Tensile test bars were cast 1.13 in. in diameter and were tested as cast.

190. Wrought iron and steel. Wrought iron is made by burning the impurities out of cast iron. In the process the foundry pig iron from the blast furnace is first placed in the puddle furnace, where it is heated and stirred until the carbon, silicon, and manganese are almost entirely burned out. When taken from the furnace, the iron is in the form of a pasty ball, which is squeezed until the cinders are expelled, after which it is rolled into bars known as muck bars. After being reheated it is rolled again, and is then known as merchant bar. If a better grade of wrought iron is desired, the merchant bar is reheated and rolled again, when it is known as best iron; if rolled again, the quality is still further improved.

In methods used by the ancients the ore and fuel were placed together. This necessitated a pure fuel and did not admit of rapid manipulation; it is still used, however, to obtain wrought iron of a pure quality, and in obtaining very fine grades of steel.

Wrought iron is a tough, ductile material showing an elongation of from 18 to 30 per cent in 8 in. Its tensile and compressive strength at the elastic limit is about 28,000 lb./in.² for high-grade wrought iron, and about 23,000 lb./in.² for common wrought iron. Its maximum tensile strength varies from 44,000 lb./in.² to 64,000 lb./in.². The material is much more elastic than cast iron, its modulus of elasticity in tension being about 28,000,000 lb./in.², and in shear about 10,000,000 lb./in.².

191. Manufacture of steel. Tool steel is made by recarbonizing wrought iron by heating it in a charcoal fire for several days at a temperature of about 3000° F. During this process part of the carbon is absorbed by the iron, the product being known as blister steel. This is then melted and cast into ingots, from which the merchantable bars are rolled or hammered. The two steps in this process are usually combined into one.

Open-hearth steel is obtained by mixing molten pig iron with scrap iron or scrap steel in an open-hearth furnace. The added scrap is low in carbon, and thus lowers the percentage of carbon in the mixture. To offset this, the desired amount of carbon is introduced by adding speigeleisen.

Bessemer steel is made directly from pig iron in a Bessemer converter, no additional fuel other than the impurities in the metal being used. These impurities are burned out to the desired extent by forcing jets of hot air through the liquid metal. Since in this method the molten iron is taken directly from the blast furnace, a considerable saving in the cost of production is effected, by reason of which the Bessemer process has revolutionized the steel industry.

In both the open-hearth and Bessemer processes the liquid steel is cast into ingots, which are rolled into the desired shapes.

192. Composition of steel. The physical properties of steel are largely modified by the relative proportions in which the various ingredients are present.

Carbon. Increasing the amount of carbon in steel has, in general, the effect of increasing its modulus of elasticity and its ultimate strength. From a series of tests made on carbon steel, in which the percentage of carbon varied from 0.08 to 1.47, Professor Arnold found that the elastic limit varied from 27,300 lb./in.² to 72,300 lb./in².; the tensile
strength, from 47,900 lb./in.² to 124,800 lb./in.²; the elongation, from 46.6 per cent to 2.80 per cent; and the reduction of area, from 74.8 per cent to 3.30 per cent.* The following table gives average values of the ultimate strength in both tension and compression for Bessemer and open-hearth steel containing different percentages of carbon.

</table>

Carbon tool steel furnishes material for springs, saws, chisels, files, etc. When annealed it is strong in both tension and compression, and quite ductile, but when heated to the critical temperature and then quenched it becomes weak, brittle, and hard.

Silicon in carbon steel and wrought iron generally strengthens the material, but decreases its ductility. In amount it is usually less than 0.6 per cent.

Manganese increases both the strength and hardness of carbon steel and wrought iron, and decreases ductility to some extent. More than 1.5 per cent makes the steel very brittle. When manganese is present in quantities of from 10 to 15 per cent, with a small amount of carbon, say 1 per cent, the steel becomes hard and is used for castings and forgings. When annealed the castings are both strong and tough enough to resist wear.

Sulphur increases the brittleness and hardness of steel and wrought iron, and is, in general, a very harmful ingredient. Low percentages of sulphur somewhat increase the tensile strength.

Phosphorus increases hardness and tensile strength, but decreases ductility, making the metal weak under impact and unsuited for anything but static loads.

Nickel is added to steel up to about 35 per cent. When the percentage of nickel is low, say about 5 per cent or less, the elastic limit and tensile strength are raised without any reduction in the elongation or in the contraction of area. Because of this increase in strength without loss of ductility, nickel steel is used in the manufacture of armor plate, armor-piercing shells, boiler tubes, shafting, etc., where a steel is needed which shall combine great strength with toughness. The following table shows the relative properties of low carbon steel tubes and high nickel steel tubes.*

<table>

The same authority also gives the average tensile strength of sixteen steel tubes, composed of 25 per cent nickel, as 108,913 lb./in.² for unannealed specimens, and 97,300 lb./in.² for annealed specimens. The elongation in the former case was 28 per cent in 7.87 in., and in the latter case 38 per cent in the same length.

Tests made by the Watertown Arsenal on a 3.37 per cent nickel steel gave an average elastic limit of 56,700 lb./in.² and a tensile strength of 90,300 lb./in.².†

193. Steel castings are made both by the Bessemer and open-hearth processes. In the Bessemer process the iron is first reduced to wrought iron, and then spiegelisen, or ferromanganese, added to furnish the necessary carbon. Aluminum may be added to prevent blowholes. The metal is cast in the same way as in making other castings.

On page 242 is given a report of a series of tests made at the Watertown Arsenal on castings for gun carriages.‡ The elastic limit varied from 47,000 lb./in.² to 21,500 lb./in.², and the tensile strength from 81,000 lb./in.² to 43,000 lb./in.². Good average values might be given as 30,000 lb./in.² at the elastic limit and 66,000 lb./in.² at the

† Watertown Arsenal Report, 1899.

194. Modulus of elasticity of steel and wrought iron. The modulus of elasticity of steel and wrought iron is about the same in tension as in compression. For steel, 30,000,000 lb./in.² is usually taken as a good average value for tension and compression, and about two fifths of this amount, or from 10,000,000 to 12,000,000 lb./in.², for shear; for loads below the elastic limit it is always the ratio of stress to deformation.

From a series of tests reported in the Trans. Amer. Soc. Civ. Eng., Vol. XVII, pp. 62-63, the following average values are found.

<table>

195. **Standard form of test specimens.** It was pointed out in Article 20 that the form of the test specimen had considerable effect upon the results obtained from tests. To eliminate this factor, standard dimensions for both cylindrical and rectangular test specimens have been adopted. These are shown in Fig. 153.

196. **Specifications for wrought iron and steel.** In order that the student may form some idea of the strength required by manufacturers for different grades of wrought iron and steel, quotations are given below from the proposed specifications of the American Society for Testing Materials.

### WROUGHT IRON

<td>25</td>
<td>22</td>
</tr>
</tbody>
</table>
The above grades of steel, known as structural steel for bridges and ships, must conform to certain bending tests. For this purpose the test specimens shall be 1\frac{1}{2} in. wide, if possible, and for all material \frac{1}{2} in. or less in thickness the test specimen shall be of the same thickness as that of the finished material from which it is cut; but for material more than \frac{3}{4} in. thick the bending test specimen may be \frac{1}{2} in. thick. Rivet rounds shall be tested full size as rolled.

Rivet steel shall bend cold 180° flat on itself without fracture on the outside of the bent portion.

Soft steel shall bend cold 180° flat on itself without fracture on the outside of the bent portion.

Medium steel shall bend cold 180° around a diameter equal to the thickness of the specimen tested, without fracture on the outside of the bent portion.

**STEEL AXLES**

Steel for axles shall be made by the open-hearth process and shall be divided into the following classes: (a) car, engine-truck, and tender-truck axles; and (b) driving axles. For (a) no tensile tests shall be required, but for driving axles the following physical properties shall be required.

<table>
<thead>
<tr>
<th>Tensile strength, lb./in.(^2)</th>
<th>Carbon Steel</th>
<th>Nickel Steel</th>
</tr>
</thead>
<tbody>
<tr>

<td>7</td>
<td>43</td>
<td>6\frac{1}{2}</td>
</tr>
</tbody>
</table>

To be accepted, the axle must stand the blow without rupture and without exceeding, as the result of the first blow, the deflection stated.
DESCRIPTION OF THE DROP TEST

The points of support on which the axle rests during tests shall be 3 ft. apart from center to center; the hammer must weigh 1640 lb.; the anvil, which is supported on springs, must weigh 17,500 lb.; it must be free to move in a vertical direction; the springs upon which it rests must be twelve in number, of the kind specified; and the radius of supports and of the striking face on the hammer in the direction of the axis of the axle must be 5 in.

The deflections are measured by placing a straightedge along the axle, properly held at the supports, and measuring the distance from this straightedge to the axle both before and after the blow. The difference between the two measurements gives the deflection.
CHAPTER XIII

LIME, CEMENT, AND CONCRETE

197. Quicklime. If calcium carbonate (ordinary limestone) is heated to about 800° F., carbon dioxide is driven off, leaving an oxide of calcium, which is known as quicklime. This has a great affinity for water and slacks upon exposure to moisture. Slacked lime when dry falls into a fine powder.

Lime mortar is formed by mixing slacked lime with a large proportion of sand. Upon exposure to the air this mortar becomes hard by reason of the lime combining with carbon dioxide and forming again calcium carbonate, the product being a sandy limestone. Lime mortar is used in laying brick walls and in structures where the mortar will not be exposed to water, since it will not set, i.e. combine with carbon dioxide, under water.

198. Cement. When limestone contains a considerable amount of clay, the lime produced is called hydraulic lime, for the reason that mortar made by using it will harden under water. If the limestone contains about 30 per cent of clay and is heated to 1000° F., the carbon dioxide is driven off, and the resulting product, when finely ground, is called natural cement. When about 25 per cent of water is added, this cement hardens, because of the formation of crystals of calcium and aluminum compounds.

If limestone and clay are mixed in the proper proportions, usually about three parts of lime carbonate to one of clay, and the mixture roasted to a clinker by raising it to a temperature approaching 3000 F., the product, when ground to a fine powder, is known as Portland cement. The proper proportion of limestone and clay is determined by finding the proportions of the particular clay and stone that will make perfect crystallization possible. In the case of natural cement the lime and clay are not present in such proportions as to form perfect crystals, and consequently it is not as strong as Portland cement.
The artificial mixing of the limestone and clay in the manufacture of Portland cement is accomplished in different ways. Throughout the north central portion of the United States large beds of marl are found, and also in the same localities beds of suitable clay. This marl is nearly pure limestone, and is mixed with the clay wet. Both the marl and clay are pumped to the mixer, where they are mixed in the proper proportions. The product is then dried, roasted, and ground.

Most American Portland cements, however, are made by grinding a clay-bearing limestone with sufficient pure limestone to give the proper proportions. After being thoroughly mixed the product is roasted and ground to a powder.

Slag cement (Puzzolan) is made by thoroughly mixing the granulated slag from an iron blast furnace with slacked lime, and then grinding the mixture to a fine powder. Slag cements are usually lighter in color than the Portland cements, and have a lower specific gravity, the latter ranging from 2.7 to 2.8. They are also somewhat slower in setting than the Portland cements, and have a slightly lower tensile strength. They are not adapted to resist mechanical wear, such as would be necessary in pavements and floors, but are suitable for foundations or any work not exposed to dry air or great strain.

True Portland cement may be made from a mixture of blast-furnace slag and finely powdered limestone, the mixture being burned in a kiln and the resultant clinker ground to powder. Both the Portland and the Puzzolan cements will set under water, i.e. they are hydraulic.

199. Cement tests. The many different processes of mixing, roasting, grinding, and setting through which a cement must pass, require that a number of tests be made to determine whether or not these have been well done. If the grinding has been improperly done, or if any of the other operations of manufacture have been neglected, the product may be very weak, or even worthless. To make sure that all the steps in the manufacture of the cement have been properly carried out, engineers make use of the following tests: (a) test of soundness; (b) test of fineness; (c) test of time of setting; (d) test of tensile strength.

200. Test of soundness. One test for soundness consists in boiling a small ball of neat cement in water for three hours, and noting whether or not checks or cracks occur. If the cement contains too
much free lime, the ball will disintegrate and show signs of crumbling. The ball of cement is kept under a damp cloth for twenty-four hours before boiling. This test is not regarded with favor by many engineers.

201. Test of fineness. If the grinding has not been properly done, large particles of clinker remain, which act as a sand or other foreign substance and thus weaken the cement. The test for fineness is made by sifting the cement through different sieves; usually all of it is required to pass through a sieve of 50 meshes to the inch, and a smaller amount through sieves of 80 and 100 meshes. About 75 per cent should pass through a 200-mesh sieve (see Article 206).

202. Test of time of setting. It is important that a cement should not set too quickly or too slowly. A test for time of setting, known as Gillmore's test, has been standardized in the United States, and consists in applying to a small cement pat given weights supported by points of specified area (Fig. 154). The cement pat is made by mixing a portion of neat cement with the proper amount of water, mounting this on a piece of glass, and smoothing it until the middle is half an inch thick and the edges are smooth and tapering. The pat is then kept under a damp cloth to prevent injury by sudden changes in temperature, or too high temperature, of the surrounding air. When this pat will hold without appreciable indentation a quarter-pound weight supported by a wire \( \frac{1}{2}\) in. in diameter, it is said to have acquired its initial set. It is said to have acquired its final set when a one-pound weight supported by a wire \( \frac{3}{4}\) in. in diameter will not appreciably indent the surface.

When a pat prepared as indicated above checks or warps, it indicates that the cement in setting changes volume too rapidly. For many pieces of work a slow-setting cement cannot be used; but a cement which sets too quickly is likely to contain too much free lime, and should be very carefully tested before being used. In general, the time of final setting for natural cement should not be less than thirty minutes nor more than three hours.

The table given on page 250 shows the time of setting of different brands of cement.* The student is also referred to the standard specifications for cement given in Article 206.

203. Test of tensile strength. The tensile strength of a cement is made by testing briquettes of neat cement or cement mortar in tension. The briquettes are made in standard molds (Fig. 155),
Fig. 154. — Weights for Testing Briquettes

Fig. 156. — Cement Testing Machine
which provide for a cross section of one square inch at the middle, with thicker ends for insertion in the jaws of the testing machine. This test requires considerable expertness to get satisfactory results, for the proper mixing and tamping into the molds can only be satisfactorily done by one of considerable experience. After molding, the briquettes are kept under a damp cloth for about twenty-four hours and then under water until tested.

Many machines are now made for testing the tensile strength of cement, most of them being light enough to be portable. A new automatic machine, manufactured by the Olsen Testing Machine Company of Philadelphia, is shown in Fig. 156. The machine is operated by first placing the briquette in position and balancing the beam at the top. The load is then applied by allowing the shot to run from the pan on the right end of the beam. The spring balance gives the exact weight of the shot and, consequently, the tensile stress on the briquette at any time during the test. After the briquette is broken the tensile strength in pounds per square inch is recorded on the dial.

204. **Speed of application of load.** It has been found that the rapidity with which the load is applied has considerable effect upon the results obtained in making tension tests of cement. The following table clearly shows this effect.*

205. Compression tests. Compression tests of cement are made in Europe, but not generally by engineers in the United States, as the tensile test is thought quite as valuable as the compression test in giving results indicative of the strength of the cement. Compression tests are made upon the ends of the specimen broken in tension, or upon specially prepared cement cubes. The use of the broken ends of the briquette insures the same material for the compression test as was used in the tension test. The table on page 252 gives the compressive strength of several brands of cement.* The tests were made by compressing halves of briquettes broken in tension, and both the tensile and compressive strengths are given.

206. Standard specifications for cement. The following is a copy of the standard specifications for cement recently proposed by the American Society for Testing Materials.

NATURAL CEMENT

This term shall be applied to the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas.

Specific gravity. The specific gravity of the cement, thoroughly dried at 100° C., shall be not less than 2.8.

Finessness. It shall leave by weight a residue of not more than 10 per cent on the No. 100 sieve, and not more than 30 per cent on the No. 200 sieve.

Time of setting. It shall develop initial set in not less than ten minutes, and hard set in not less than thirty minutes nor more than three hours.

Tensile strength. The minimum requirements for tensile strength for briquettes 1 in. square in cross section shall be within the following limits, and shall show no retrogression in strength within the periods specified.†

<table>

<td>25–75 lb.</td>
<td>28 days (1 &quot; &quot; &quot; 27 &quot; &quot; )</td>
</tr>
</tbody>
</table>

* Watertown Arsenal Report, 1901.
† For example, the minimum requirement for the twenty-four-hour neat cement test should be some value within the limits of 50 and 100 lb., and so on for each period stated.
STRENGTH OF MATERIALS

Constancy of volume. Pats of neat cement about 3 in. in diameter, ½ in. thick at the center, tapering to a thin edge, shall be kept in moist air for a period of twenty-four hours.

(a) A pat is then kept in air at normal temperature.

(b) Another is kept in water maintained as near 70° F. as practicable.

These pats are observed at intervals for at least twenty-eight days, and, to satisfactorily pass the tests, should remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

PORTLAND CEMENT

This term is applied to the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials, and to which no addition greater than 3 per cent has been made subsequent to calcination.

Specific gravity. The specific gravity of the cement, thoroughly dried at 100° C., shall be not less than 3.10.

Fineness. It shall leave by weight a residue of not more than 8 per cent on the No. 100 sieve, and not more than 25 per cent on the No. 200 sieve.

Time of setting. It shall develop initial set in not less than thirty minutes, and hard set in not less than one hour nor more than ten hours.

Tensile strength. The minimum requirements for tensile strength for briquettes 1 in. square in section shall be within the following limits, and shall show no retrogression in strength within the periods specified.*

(a) A pat is then kept in air at normal temperature and observed at intervals for at least twenty-eight days.

(b) Another pat is kept in water maintained as near 70° F. as practicable, and observed at intervals for at least twenty-eight days.

*For example, the minimum requirement for the twenty-four-hour neat cement test should be some value within the limits of 150 and 200 lb., and so on for each period stated.
(c) A third pat is exposed in any convenient way in an atmosphere of steam, above boiling water, in a loosely closed vessel for five hours. These pats, to satisfactorily pass the requirements, shall remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

**Sulphuric acid and magnesia.** The cement shall not contain more than 1.75 per cent of anhydrous sulphuric acid \((SO_3)\), nor more than 4 per cent of magnesia \((MgO)\).

### 207. Concrete.

When cement mortar is mixed with certain percentages of broken stone, gravel, or cinders, the mixture is called **concrete**. The amount and kind of stone or other material to be used depends upon the use to be made of the finished product. Concrete is rapidly coming into favor as a building material, and is replacing brick and stone in many classes of structures. If properly made it is a much better building material than either of the latter, and has an additional advantage in the fact that it can be handled by unskilled labor and may be readily molded into any desired form. In view of these facts, a study of its properties is of the greatest importance.

### 208. Mixing of concrete.

In making concrete, the sand and cement are first thoroughly mixed and gauged with the right amount of water. The stone, having previously been moistened, is then added, and the whole is thoroughly mixed until each piece of stone is coated with the cement mortar. These two operations are often combined into one. The amount of water to be used in making the mortar depends upon the character of the concrete desired. A medium concrete may be obtained by adding enough water so that moisture comes to the surface when the mortar is struck with a shovel.

After mixing, the concrete is tamped, or rammed, into position. This tamping should be thoroughly done, since in no other way can as dense a mixture be obtained. It is desirable that all the voids (spaces between the broken stone) should be filled as compactly as possible with mortar.

### 209. Tests of concrete.

Concrete is usually tested in compression, and for this purpose 6-inch cubes * are made, composed of cement, sand, and broken stone in the proportions of 1: 2: 4 or 1: 3: 6. In some cases the proportion to be used in the particular work concerned is also used in making the test cubes. These cubes are made in molds and allowed to set in air, or part of the time in air and the

---

* Cylinders or larger cubes are also sometimes used.
remainder in water, until tested. The kind of cement as well as its physical properties must be known; also the kind of sand and stone and the degree of fineness of each.

When ready for testing, the concrete cubes are placed in the testing machine, bedded with plaster of Paris or thick paper, and tested in compression. The load at first crack and the maximum load are noted.

The table on the opposite page is a report of a series of tests made at the Watertown Arsenal on Akron Star cement concrete in compression.* It will be noticed that the ultimate strength varied from 600 lb./in.\(^2\) to 2700 lb./in.\(^2\).

The table on page 258 is taken from the same volume as the preceding, and summarizes the results of tests on concrete made from different kinds of cement. Various kinds of broken stone were used, including broken brick, and the ultimate strength ranged from 600 lb./in.\(^2\) to 3800 lb./in.\(^2\). In making comparisons from the table as to strength several things must be noted, namely, the kind and strength of the cement, the proportions and character of the sand and gravel, the treatment after making, and the age when tested; in other words, a complete history of the materials and their treatment should be known. In the following table the cubes tested were set in air, in a dry, cool place.

The location and character of the structure will often determine the kind of materials to be used in making the concrete. Thus, on account of convenience, pebbles are sometimes used with the sand in which they are found. This reduces the cost of the concrete, but usually impairs its strength, as the proportions of sand and stone as they occur in nature are not likely to be such as to be suitable for concrete. Theoretically, to get the best results the proportions should be such that the cement fills the spaces between the grains of sand, and the mortar fills the spaces between the pieces of stone.

In any particular case the cost of material, strength of the concrete, and service required of the structure must determine what proportions shall be used.

**Problem 174.** A concrete cube 12 in. high when tested in compression sustained a load of 324,000 lb. at first crack, and 445,200 lb. at failure. Find the intensity of the compressive stress in lb./in.\(^2\) at first crack and at failure.

* Watertown Arsenal Report, 1901.

**Note:** The values in the table represent the compressive strength of concrete in pounds per square inch (lb./in.²) at different ages and weights. The columns represent the brand of cement, composition, age, weight, and dimension details. The ultimate strength is also indicated for comparison.
210. Modulus of elasticity of concrete. Concrete is so imperfectly elastic that the modulus of elasticity varies with the stress. It also changes with the age of the material and with the change in proportions of cement, sand, and stone.

The variation in the modulus of elasticity with the stress makes it difficult to make theoretical computations in which the modulus of elasticity is involved, as, for instance, in such problems as arise in connection with reënforced concrete beams, etc.*

* For the method of computing the modulus of elasticity for materials which do not conform to Hooke's law see Article 65.
The strain diagram of concrete in compression, shown in Fig. 157, illustrates the fact that there is no well-defined elastic limit, and that the modulus of elasticity changes as the load increases.

The table on page 259 also illustrates the variation in the modulus of elasticity of concrete in compression.* In the first ten tests the cement used in making the test specimens was Alpha Portland, in the next sixteen it was Germania Portland, and in the remaining ones Alsen Portland.

**Problem 175.** From the strain diagram of concrete in compression shown in Fig. 157, compute the modulus of elasticity at 1800 lb./in.\(^2\) and at 2400 lb./in.\(^2\). The height of the block tested was 10 in.

**Problem 176.** A concrete beam 6 in. \(\times\) 6 in. in cross section, and with a 68-in. span, is supported at both ends and loaded in the middle. The load at failure is 1008 lb. Find the maximum fiber stress.

The table shows the variation of the modulus of elasticity for different stresses. Lehigh Portland cement was used and the cubes were set in air.

212. Concrete building blocks. During the past few years great progress has been made in the manufacture and use of concrete building blocks. In comparison with stone these have the advantage of cheapness, ease of manipulation, and beauty of the finished product. A type of concrete building block is shown in Fig. 158, and illustrates the general characteristics of such blocks.

Few tests have been made on concrete blocks, and but little is known as to their durability. The following table is a report of a series of tests made at the University of Michigan.† The blocks were first tested in flexure, and then an uninjured portion of the block was tested in compression. Blocks 3, 4, 5, and 6 were from the same mixture, and were composed of one part cement, two parts sand, and three parts broken stone. They were all tested after four months.

Problem 177. A concrete building block 24 in. in length and having an effective cross section of 8 in. x 10 in. minus 4 in. x 10 in. is tested by being supported at both ends and loaded in the middle. The load at failure is found to be 5000 lb. Find the maximum fiber stress, the height of the block being 10 in.

* Watertown Arsenal Report, 1903. † Concrete, February, 1905.
CHAPTER XIV

REÉNFORCED CONCRETE

213. Object of reënforcement. The fact that concrete is much stronger in compression than in tension has led to attempts to increase its tensile strength by imbedding steel or iron rods in the material. This metal reënforcement is so designed as to carry most of the tensile stress, and thus plays the same part in a concrete structure as the tension members play in a truss.

It has been found by experiment that reënforced concrete beams may be stressed in flexure far beyond the elastic limit* of ordinary concrete, and even beyond the stress which would rupture the same beam, if not reënforced, without appreciable injury to the material. M. Considère, one of the leading French authorities on the subject, reports a test of this kind, in which he found that concrete taken from the tensile side of a reënforced concrete beam tested in flexure was uninjured by the strain. Professor Turneaure, of the University of Wisconsin, has found that minute cracks occur on the tension side of a reënforced concrete beam as soon as the fiber stress reaches the point at which non-reënforced concrete would crack.† Experiments of this kind seem to indicate that the metal reënforcement carries practically all of the tensile stress, as cracks in the concrete must certainly reduce its tensile strength to zero at this point.

214. Corrosion of the metal reënforcement. The maintenance of the increased strength of concrete due to the metal reënforcement depends upon the preservation of the metal. The corrosion of metal imbedded in concrete is thus a matter of the greatest importance in connection with reënforced concrete work. It has been found that metal thus protected does not corrode even though the concrete be

* As indicated in Chapter XIII, concrete shows no well-defined elastic limit, i.e. the material does not conform to Hooke's law. In this case elastic limit means the arbitrary point beyond which the deformations are much more noticeable than formerly.

subjected to the severest exposure. However, the existence of cracks on the tension side of reënforced beams makes the exposure of the metal rods possible, and thus adds a new danger to the life of the beam; but the small hairlike cracks that occur after the elastic limit of the concrete has been passed probably have no effect in this respect. When they become large enough to expose the reënforcement, the strength of the beam is endangered.

215. Adhesion of the concrete to the reënforcement. When a reënforced concrete beam is subjected to stress, there is always a tendency to shear horizontally along the reënforcement. This is prevented in part by the adhesion between the steel and concrete. Failure often occurs, due to this horizontal shear, especially when the beam is over-reënforced, i.e. when the area of cross section of the reënforcement is large as compared with the total area of cross section of the beam. When plain round or square rods are used, the adhesion between the steel and concrete furnishes the only bond. For commercial purposes, however, various forms of reënforcement are ordinarily used to increase this bond. Four of these commercial types are illustrated in Fig. 159. The Johnson, Thacher, and Ransome bars are provided with projections and indentations to prevent the bar from pulling out of the concrete, while the Kahn bar, by means of the projecting arms that extend upward along the lines of principal stress in the beam, is also designed to act as a truss. Several other commercial types of bar are also in use, but all are provided with projections or indentations of some kind to prevent slipping.

Many tests have been made to determine the force necessary to pull the various forms of rods from concrete. The following table gives the results of pulling-out tests made by Professor Edgar Marburg, of the University of Pennsylvania.* The rods in this case were imbedded centrally in 6 in. x 6 in. concrete prisms 12 in. long, and were tested after thirty days. In most cases, except in that of the

plain rods, failure was due to the breaking of the rods or the cracking of the concrete. On account of the projections on some of the rods these can hardly be called adhesion tests, but should more properly be called pulling-out tests.

As might be expected, the plain rods show the lowest values, since any reduction in cross section of the rod, due to the tensile stress upon it, largely destroys the adhesion of the concrete. Square reënforcing rods, or those that present sharp angles, are likely to cause initial cracks upon the shrinkage of the concrete. To have the strongest bond a rod should be round, with rounded projections.

216. **Area of the metal reënforcement.** Since the small hairlike cracks mentioned in Article 213 occur early during the flexure of a reënforced concrete beam, it is evident that in designing little can be allowed for the tensile strength of the concrete. The problem becomes one of opposing the compressive strength of the concrete and the tensile strength of the reënforcement. This means that knowing the safe compressive strength of the concrete and the area of the concrete in compression, sufficient steel must be used to carry safely a tensile load equal to the compressive load on the concrete. Professor Marburg, in the paper referred to in the preceding article,
STRENGTH OF MATERIALS

gives 1600 lb./in.² for the compressive strength of 6-inch cubes thirty days old. A slightly higher value was found for cubes from a different mixture.

From an investigation of the tensile strength of steel reënforcing bars, the writer referred to above obtained the following values.

<table>
<thead>

With a 1–3–6 concrete a 1.5 per cent reënforcement of steel, having an elastic limit of 33,000 lb./in.², and a 1.0 per cent reënforcement of steel, having an elastic limit of 55,000 lb./in.², has been used without developing the full compressive strength of the concrete.* In this case the percentage is figured on the area of concrete above the center of the metal reënforcement. This percentage may also be figured on the area of cross section of the beam.

217. Position of the neutral axis in reënforced concrete beams.

In Article 210 it was pointed out that the modulus of elasticity of concrete in compression is not constant. This indicates that in the case of flexure the position of the neutral axis changes with the stress, at first lying near the center, but moving toward the compression side as the load is increased. In a reënforced concrete beam the neutral axis also undergoes a displacement, due to the non-homogeneity of the cross section, since the moduli of elasticity of steel and concrete are not the same. In this case, if the beam is reënforced only on the tension side, and the metal reënforcement is designed to carry all the tensile stress, the neutral axis usually lies nearer the tension side of the beam than the compression side.†

From tests made at Purdue University, Professor Hatt found the ratio of the moduli of elasticity of steel in tension to concrete in

---

† See article by S. E. Scolem, entitled "Rational Formulas for the Strength of a Concrete Steel Beam," Engineering News, July 30, 1903.
compression, for certain grades of material to be as follows.* The use of this ratio is exemplified in the following article.

218. Flexure of reënforced concrete beams. Two general theories of the flexure of reënforced concrete beams have been advanced. In one it is assumed that the stress over any cross section of the beam varies as the distance from the neutral axis, assumed as constant (Articles 41 and 48). In the other the stress acting on any cross section of the beam is assumed to vary as the ordinates to a parabola (Fig. 160). The following analysis is based on the parabolic assumption, and is due to Professor Hatt, of Purdue University, the method followed being that of M. Considère.†

Besides the assumptions of the common theory of flexure (Article 38) and the parabolic distribution of stress, this analysis is based on the following additional assumptions.

1. The values of the moduli of elasticity obtained from simple tensile and compressive tests apply to the materials under consideration.
2. There is no slipping between the concrete and the steel reënforcement.
3. There are no initial stresses in the concrete due to shrinkage while setting.

Let

\[ l = \text{length of span}, \]
\[ b = \text{width of cross section}, \]
\[ h = \text{depth of beam}, \]
\[ hv = \text{distance from compression face to neutral axis}, \]

* Jour. Western Soc. Eng., June, 1904.  † Ibid.
\[ h_u = \text{distance from compression face to center of gravity of metal reënforcement}, \]
\[ r = \text{ratio of area of metal to total area of cross section}, \]
\[ E_s, E_c, E_t = \text{moduli of elasticity of steel, of concrete in compression, and of concrete in tension respectively}, \]
\[ n = \frac{E_c}{E_s}, \quad k = \frac{E_c}{E_t}, \]
\[ p_* = \text{unit stress in metal reënforcement}, \]
\[ p_c = \text{unit compressive stress in outer fiber of concrete}, \]
\[ p_t = \text{unit tensile stress in outer fiber of concrete}. \]

The reënforcement is supposed to be in the tension flange, as shown in Fig. 160, and \( E_s, E_c \) are measured at stresses \( p_c, p_t \) respectively.

Equating the sum of the horizontal forces to zero, and remembering that the strain diagrams are arcs of parabolas, there results the equation
\[
\frac{3}{4} p_c \epsilon_c = \frac{3}{4} (1 - v) p_t + rp_*, \tag{111}\]
If the cross section remains plane during flexure, we also have
\[
p_c = \frac{n v p_t}{1 - v}, \quad p_* = \frac{k (u - v) p_t}{1 - v}. \tag{112}\]
Substituting these values in (111), and solving the resulting quadratic for \( v \), we have
\[
v = -\frac{1}{2} (4 + 3 r k) + \sqrt{4 n + \frac{9}{4} v^2 k^2 + 6 r k [1 + u (u - 1)]} \frac{2 (n - 1)}{2 (n - 1)}, \tag{113}\]
which determines the position of the neutral axis. Taking moments about this neutral axis, the moment of resistance of the cross section is found to be
\[
M = p_b h^2 \left( \frac{5 (1 - v)^2}{12} + \frac{5 n v^3}{12 (1 - v)} + \frac{r k (u - v)^2}{1 - v} \right). \tag{114}\]

Equations (113) and (114) suffice for the solution of problems in which the beam has not been bent sufficiently to produce cracks on the tension side.* When such cracks occur the validity of the parabolic law for the variation of stress on the tension side of the neutral

* These formulas have been recommended by a committee of the American Railway Engineering and Maintenance of Way Association.
axis is destroyed, and in this case equations (111) and (114) must be modified by neglecting the tensile stress in the concrete.

The following table gives a comparison of the preceding theory with experiment. The beams reported in the table were made and tested at Purdue University.* They were 8 in. x 8 in. x 80 in. in size, and were composed of one part cement, two parts sand, and four parts broken stone. In each case the elastic limit of the reënforcement was reached before the concrete failed in compression.

The quantity denoted by $K$ in the last two columns of the table is the quantity in parenthesis in equation (114), viz.

$$K = \frac{5(1-v)^2}{12} + \frac{5nv^2}{12(1-v)} + \frac{rk(u-v)^2}{1-v}.$$

**Problem 178.** A reënforced concrete beam 8 in. x 10 in. in cross section, and 15 ft. long, is reënforced on the tension side by six $\frac{1}{2}$-in. plain steel rounds. The steel has a modulus of elasticity of 30,000,000 lb./in.\(^2\), and the center of the reënforcement is placed 2 in. from the bottom of the beam. Assuming that $E_s = 300,000$ lb./in.\(^2\), $E_c = 3,000,000$ lb./in.\(^2\), and $p_e = 2500$ lb./in.\(^2\), find from formulas (113) and (114) the position of the neutral axis and the moment $M$.

**Note.** The moment $M$ corresponds to the moment $\frac{p_f}{e}$ obtained from the consideration of the flexure of homogeneous beams; that is to say, $M$ is the moment of resistance of the beam (see Article 44).

**Problem 179.** For a stress $p_e = 2700$ lb./in.\(^2\) on the outer fiber of concrete in the beam given in Problem 178, find the stress $p_s$ in the steel reënforcement.

**Problem 180.** Using the data of Problem 178, locate the neutral axis and find the value of the moment of resistance $M$ under the assumption that the stresses in the concrete vary linearly.

*Jour. Western Soc. Eng., June, 1904.*
Problem 181. Find the single central load that can be supported by the beam in Problems 178 and 179, assuming the values given as safe values.

Hint. Use the formula \( M = \frac{Pl}{4} \).

Problem 182. In Problem 178 suppose that the metal reinforcement has an elastic limit of 45,000 lb./in.\(^2\) but that its area is not known, the rest of the data remaining the same. Neglecting the tensile strength of the concrete, find the amount of steel reinforcement necessary to make the beam equally strong in tension and compression.

219. Linear variation of stress. Assuming the straight-line law of the distribution of stress (Articles 41 and 42), the equations corresponding to (111) and (114) are

\[
\frac{1}{2} \nu p_c = \frac{1}{2} (1 - \nu) p_t + r p_s,
\]

and

\[
M = \frac{1}{3} b h^2 (1 - \nu)^2 p_t + \frac{1}{3} b h^2 v^2 p_c + b h^2 (u - \nu) p_s,
\]

while the expressions for \( p_c \) and \( p_s \) given in equation (112) are unchanged. Substituting the values of \( p_c \) and \( p_s \) from (112) in (115), the expression for the location of the neutral axis becomes

\[
v = -\frac{(1 + rk) + \sqrt{(1 + rk)^2 + (1 + 2 rku)(n - 1)}}{n - 1}.
\]

The above formulas are somewhat simpler than those obtained under the parabolic assumption as to the distribution of stress, and for this reason are preferred by many engineers. In either case the additional assumption that the beam is also reinforced on the compression side adds considerably to the complexity of the analysis.

The following table gives the calculated stress in the steel reinforcement for the tests reported.* In these calculations the parabolic variation of stress was assumed for the compression side. The assumption of the straight-line variation was found to give stresses differing by only 2 per cent.

Numerous empirical formulas for the calculation of reënforced concrete beams have been proposed by Christophe, Thacher, A. L. Johnson, and others. For a complete discussion of the subject the student is referred to Chapter II of Buel and Hill's book on reënforced concrete.†

### 220. Other uses of reënforced concrete

Reënforced concrete is now used for foundations, piers, columns, floors, chimneys, standpipes, reservoirs, dams, tunnels, sewers, bins, bridges, piles, railroad ties, fence posts, and many other constructions. Its recent development along all these lines has been very rapid, but many more investigations will be necessary before its physical properties are definitely fixed. Until recently no attempt was made in this country to standardize experimental results in this line, but the work is now being done under the direction of a joint committee from the various national societies interested, and it is hoped that within a short time much more satisfactory information will be available.
221. Limestone. Limestone is principally a carbonate of lime, made up of seashells that have been deposited from water during past geological times. Its method of formation has much to do with its value as a building material. If it contains no thin layers of clay or shale (sedimentary planes), it is likely to be fairly homogeneous in structure. But if layers of shale, however small, occur, the material is much more quickly weathered. This is especially true if the stone be placed at right angles to the position it occupied in the quarry.

Thin planes of foreign substances are likely to occur in many of our best building stones, as may be seen in the rapid deterioration of seemingly first-class limestone when used as curbing. Such disintegration is caused by a lessening of the adhesion between the particles of stone.

Limestone may be composed of a great percentage of sand cemented together by calcareous matter, in which case it is called siliceous limestone. Under such circumstances chemical action may remove the cementing material, thus leaving the stone free to crumble. Marble is almost pure limestone.

Conditions to which a building stone is to be exposed will determine the character of the material to be used in any particular structure. Rapid freezing and thawing is likely to set up internal strains in the material, which may lead to future failure. These strains may be caused by unequal expansion or contraction of the particles of the stone, or by the freezing and thawing of the water in the stone. The formation of ice in the sedimentary planes accounts in a large measure for the rapid deterioration of stone.

Limestone often occurs in very thick layers, as in the case of the oölitic limestone found at Bedford, Indiana, where the layers are often from 25 to 30 ft. thick. In such cases it is a most valuable
building stone, especially for bridge piers and other structures where large masses of stone are needed. This particular limestone, unlike most others, is easily worked, being almost equal to sandstone in this respect.

When limestone is subjected to the atmosphere of a large city, where great quantities of coal are used, it is acted upon by the sulphuric acid in the air. To determine the effect of this action, a small piece of stone, well cleaned, is placed in a 1 per cent solution of sulphuric acid and left for several days. If no earthy matter appears, it may be concluded that the stone will withstand the action of the atmosphere.

222. Sandstone. Sandstone consists very largely of grains of sand (silicon) cemented together. It has been deposited from water, making it homogeneous in structure, and as it occurs in vast beds, it is very suitable for building purposes. The ease with which it may be carved and worked makes it a much more valuable building material than limestone. Various foreign substances, such as iron, manganese, etc., give to the stone a variety both in color and texture. Sandstone absorbs water much more readily than limestone, and were it not for the fact that it occurs in such thick layers, and is therefore almost free from sedimentary planes, this might be a serious objection to its use. The mean weight of sandstone is 140 lb./ft.\(^3\); that of limestone is 160 lb./ft.\(^3\).

223. Compression tests of stone. The most common test for a building stone is that of subjecting it to a direct crushing force in an ordinary testing machine. To prevent local stresses, the specimen, which is generally a well-finished cube, is usually bedded in plaster of Paris, thin pine boards, or thick paper, and the load at first crack and the maximum load are noted. The friction of the bedding against the heads of the machine tends to prevent the spreading of the specimen near these heads and thus adds to the strength of the cube. Great care is necessary in preparing the specimen, in order to get the two bearing faces exactly parallel. The stone fractures along the 30° line approximately, giving the characteristic fracture of two inverted pyramids (Figs. 161 and 162).

From a series of tests made by Buckley on the building stones of Wisconsin,* the average of ten tests on limestone gave an ultimate

* Buckley, Building Stones of Wisconsin.
strength of 23,116 lb./in.², a modulus of elasticity ranging from 31,500 lb./in.² to 1,800,000 lb./in.², and a shearing strength ranging from 1735 lb./in.² to 2518 lb./in.². The average of thirty tests on sandstone gave an ultimate strength of 4109 lb./in.², and a modulus of elasticity ranging from 32,000 lb./in.² to 400,000 lb./in.².

From a series of tests on building stone from outside the state of Wisconsin, the same report gives the ultimate strength of limestone as ranging from 3000 lb./in.² to 27,400 lb./in.², and the ultimate strength of sandstone from 2400 lb./in.² to 29,000 lb./in.². This report also gives tables showing the effect of freezing and thawing on the strength of stone, the effect of sulphuric acid on limestone, and the effect of high temperatures on building stone.

The following table shows the results of a series of compressive tests made upon limestone at the Watertown Arsenal.*

</table>

From another series of tests made at the Watertown Arsenal on a different grade of limestone, the average value of the ultimate strength was found to be 7647 lb./in.², and the modulus of elasticity to be 3,200,000 lb./in.².†

This wide range in the strength of building stone is explained by the method of its formation, which makes the character of the stone from one locality often differ entirely from that of a neighboring locality. Average values of the strength of building stone are therefore of little value, and must be used with a large factor of safety.

Problem 183. A granite block was tested in compression, the load at first crack and at maximum being 283,000 lb. and 417,400 lb. respectively. The sectional area was 16.4 in.². Find the intensity of stress at first crack and at maximum.

*Watertown Arsenal Report, 1900.  †Watertown Arsenal Report, 1894.
Fig. 161. — Result of Compression Test of Limestone

Fig. 162. — Results of Compression Tests of Sandstone
224. Transverse tests of stone. The use of stone where transverse stress is applied calls for some knowledge of its transverse strength. A stone may meet the specifications for crushing and yet fail entirely when subjected to cross bending, since a beam is in tension on one side and in compression on the other. As stone is much stronger in compression than in tension, it usually fails in tension under transverse loading.

To test the transverse strength of stone, small beams are prepared usually 1 in. square by 6 or 8 in. long. These are supported on knife-edges resting on the platform of the testing machine, and the load is applied at the center. Buckley reports limestone beams 1 in. × 1 in. × 6 in. to have a modulus of rupture of 2000 lb./in.², and sandstone beams 1 in. × 1 in. × 4 in. to have a modulus of rupture of 1000 lb./in.².

225. Abrasion tests of stone. The most extended series of tests of stone in resisting abrasion was made by Bauschinger.* Four-inch cubes under a pressure of 4 lb./in.² were subjected to the abrasive action of a disk having a radius of 19.5 in. and making 200 revolutions per minute, upon which 20 g. of emery were fed every 10 revolutions. The loss of volume in cubic inches was as follows.

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Abrasion tests of stone have never been standardized, and comparison of results of different tests must be made with a full understanding of all the conditions affecting the results.

226. Absorption tests of stone. The absorption test is made to determine the amount of water absorbed by the dry stone. In making the test the specimen is first heated for several hours at a temperature of 212° F., and then placed in water for about thirty hours. The increase in the weight of the specimen divided by its weight when dry and multiplied by 100 gives the percentage by weight of moisture absorbed. This percentage for a series of tests varied, for granite, from 1.1 to .3; for limestone, from 3.6 to 1.2; and for sandstone, from 13.8 to 1.6.

* Communications, 1884.
227. Brick and brickwork. Brick is generally made by tempering clay with the proper amount of water, and then molding into the desired shape and burning. The tempered clay is used wet, dry, or medium, depending upon the kind of brick desired, and these are classified as soft mud brick, pressed brick, or stiff mud brick respectively. The position of the brick in the kiln may also determine its classification as hard brick, taken from nearest the fire, medium brick from the interior of the pile, and soft brick from the exterior of the pile.

Paving brick is a vitrified clay brick or block somewhat larger than the ordinary brick.

228. Compression tests of brick. For this test a whole or half brick is tested edgewise or flat in much the same way as in the crushing test for building stone. The faces which are to be in contact with the heads of the testing machine are ground perfectly smooth and parallel, or are bedded, or both. If plaster of Paris is used, it should be placed between sheets of paper to prevent the absorption of water by the brick, as this may affect its strength. In any case, in testing brick or stone in compression it is desirable to use a spherical compression block for one of the heads, so that in case the faces of the test piece are not parallel the bearing will adjust itself to bring the axis of the test piece into coincidence with the axis of the machine. In this case, also, the load at first crack and the maximum load are noted. The form of the fractured specimen is also noted; it is usually that of the double inverted pyramid. An imperfect bedding may cause the specimen to split vertically into thin pieces. Cardboard cushions and soft pine boards are also used in bedding brick for testing.

The relative value of the kinds of bedding, as indicated by tests made at the Watertown Arsenal * on half bricks, may be seen from the following table.

<table>

The strength of a single brick in compression cannot be taken as a criterion of its strength in an actual structure, since its strength in that case must depend somewhat upon the mortar used. If the mortar is soft and flows (i.e. is squeezed out), the brick may fail in

* Watertown Arsenal Report, 1901.
tension, due to the lateral flow of mortar, instead of in compression. From a series of thirty-eight tests made at the Watertown Arsenal on piers of common brick, it was found that the maximum compressive strength varied from 964 lb./in.² to 2978 lb./in.². The mortar in this case was composed of one part Rosendale cement and two parts sand. The bricks used in these piers developed only one half their compressive strength. The compressive strength of soft brick may go as low as 500 lb./in.², and that of paving brick as high as 15,000 lb./in.², when used in piers.

The following table gives the results of tests of the compressive strength of common brick made at the Watertown Arsenal. The compressed surfaces were bedded in plaster of Paris, and the bricks were tested whole.

</table>

*Watertown Arsenal Report, 1884.*
The compressive strength here ranged from 5000 lb./in.\(^2\) to 18,000 lb./in.\(^2\). Average values for the strength of different kinds of brick in compression might be given as follows: soft brick, 900 lb./in.\(^2\); hard brick, 3250 lb./in.\(^2\); and vitrified brick, 17,500 lb./in.\(^2\). The latter includes paving brick.

**Problem 184.** The following bricks were tested in compression.

(a) Red face brick: sectional area, 28.45 in.\(^2\); load at first crack, 379,000 lb.; load at maximum, 384,600 lb.

(b) Vitrified brick: sectional area, 27.46 in.\(^2\); load at first crack, 72,000 lb.; load at maximum, 230,000 lb.

(c) Paving brick: sectional area, 26.72 in.\(^2\); load at first crack, 51,000 lb.; load at maximum, 148,000 lb.

Find the intensity of stress at first crack and at maximum load in each case.

**229. Modulus of elasticity of brick.** As in the case of stone and concrete, the modulus of elasticity of brick in compression is not constant, but varies to some extent with the load. On account of this variation it is hard to give average values for the modulus of elasticity of brick, especially as the materials and methods of manufacture are so varied. Therefore in stating the modulus of elasticity it is also necessary to state the corresponding load. Strictly speaking, brick, stone, and concrete have no modulus of elasticity.

The table below is the result of a series of tests of dry-pressed and mud brick, tested edgewise in compression, and gives the modulus of elasticity for loads between 1000 lb./in.\(^2\) and 3000 lb./in.\(^2\), and also at the highest stress observed.

$E (1000 - 3000) = 3,125,000$ lb./in.$^2$

$E (1000 - 8000) = 3,271,000$ lb./in.$^2$

Initial load

Draw the strain diagram. Compute the modulus of elasticity between loads of 1000 lb./in.$^2$ and 3000 lb./in.$^2$, and also between 0000 lb./in.$^2$ and 8000 lb./in.$^2$. Ultimate strength
230. Transverse tests of brick. Bricks are tested transversely by supporting them edgewise or flatwise upon two knife-edges and applying the load centrally by means of an ordinary testing machine. Care must be taken to provide suitable bearing surfaces for the knife-edges, in order to prevent local failure. In this test the upper fibers are in compression and the lower fibers in tension, and since brick is stronger in compression than in tension, failure is caused by rupture of the tension face. The fiber stress is computed from the formula

\[ P = \frac{Pe}{4I}, \]

where \( P \) is the breaking load in pounds, \( l \) is the length of span in inches, \( e \) is half the height, and \( I \) is the moment of inertia of a cross section. The fiber stress on the outer fiber at failure is usually called the modulus of rupture.

For paving brick the modulus of rupture varies from 1000 lb./in.\(^2\) to 3000 lb./in.\(^2\). For pressed brick, common brick, and medium brick the modulus of rupture varies from 300 lb./in.\(^2\) to 1200 lb./in.\(^2\).

The shearing strength of various grades of brick varies from 300 lb./in.\(^2\) to 2000 lb./in.\(^2\).

Problem 186. A brick having a depth of 2.23 in. and a breadth of 3.95 in. was loaded centrally on a span of 6 in. The ultimate load was 1045 lb. Find the modulus of rupture.

231. Rattler test of brick. Paving bricks were formerly tested in abrasion in order to determine their ability to withstand wear. This test, however, does not approach the conditions of actual service, which consist of the impact of horses' feet as well as the abrasive action of traffic. To meet these conditions the rattler test was devised. The testing machine consists of a cast-iron barrel mounted horizontally, and the test is made by placing the brick, together with some harder material, such as cast iron, in the machine and revolving it at a certain speed for a certain length of time. The ratio of the amount of material broken or worn off in this way to the original weight of the brick put into the machine indicates the value of the brick in withstanding the conditions of service.

The charge usually consists of nine paving bricks or twelve other bricks, together with 300 lb. of cast-iron blocks, the volume of the
bricks being equal to about 8 per cent of the volume of the machine. The cast-iron blocks are of two sizes, the larger being about $2\frac{1}{2}$ in. square and $4\frac{1}{2}$ in. long, with rounded edges and weighing at first $7\frac{1}{2}$ lb. The smaller are about $1\frac{1}{2}$-in. cubes, with rounded edges. About 225 lb. of the smaller size and 75 lb. of the larger size are used; 1800 revolutions are required, and must be made at the rate of about 30 per minute. *

During the first 600 revolutions the effect of the rattler action on the brick is to chip off the corners and edges. Thereafter the action is more nearly abrasive.

232. Absorption test of brick. A brick which absorbs a great amount of water is likely to be weakened and injured by frost. To measure the amount of absorption, a dry brick is taken and a determination of its absorbing capacity made, as in the case of stone (Article 226).

Ordinary brick will absorb from 10 to 20 per cent of its own weight, and paving brick from 2 to 3 per cent.

This test is now little used, since a brick that fails in the absorption test is of such poor quality that it will also fail when subjected to the crushing and cross-bending tests.

* See specifications of the National Brick Manufacturers' Association for rattler test.
233. Structure of timber. An examination of the cross section of a tree usually shows that it is made up of a rather dark interior core, or heartwood, and a lighter exterior portion, or sapwood, surrounded by the bark. In some species, such as the oaks, radial lines, called medullary rays, are seen running from the center toward the bark. If the cross section happens to be near a knot or other defect, this normal structure may be changed. If, however, no knots are present, a closer examination shows that both the sapwood and heartwood are made up of concentric rings, called annual rings, and that this appearance is due to a difference in structure. Part of the ring is seen to be denser than the rest, and, in fact, it is this difference in density which gives the section its characteristic appearance.

The annual rings in one stick of a certain species may be more widely separated than those in another stick of the same species, and the relative thickness of heartwood and sapwood may differ in different sticks. This indicates that the structure of timber varies considerably, and that therefore the physical properties also vary. This wide variation is seen in all substances found in nature, one instance of which has been shown in the case of natural stone. An investigation of the physical properties of such substances, therefore, is more difficult than that of a more homogeneous substance. However, the extensive use of timber as a structural material makes a knowledge of its structure and properties of the utmost importance.

234. Annual rings. Each of the concentric rings in timber represents the growth of one year. The inner or less dense portion represents the more rapid spring growth, while the outer dense portion represents the slower summer and fall growth. The number of rings per inch indicates the rate of growth for that number of years. If the number of rings per inch be few, the growth has been rapid and
the spring growth predominates, making the wood somewhat weak. If, on the contrary, the number of rings per inch be many, a slow growth is indicated and there is a greater amount of the dense, strong summer and fall wood. The number and character of the annual rings may thus give some idea of the strength of a piece of timber.

235. Heartwood and sapwood. The heartwood of a tree may be considered a lifeless conical core, which is increased each year by the addition of a portion of the outer sapwood. Both the sapwood and heartwood contain small tubes that extend from the roots of the tree to the branches. These tubes in the sapwood carry water charged with nourishment to the branches and growing parts of the tree. In the heartwood the tubes no longer act as conveyors, although they still contain moisture. The heartwood is the mature wood and is more valuable for structural purposes.

236. Effect of moisture. It is well known that green wood is not as strong as the same wood when seasoned, which indicates that the effect of moisture in timber is to lessen its strength. A live tree as it stands in the forest contains a great deal of moisture. When it has been cut, sawed, and dried, most of this moisture has evaporated, but considerable still remains, and however well seasoned timber may be, it will still contain some moisture.

In making tests of timber, therefore, it is necessary to determine the percentage of moisture in order that the results may be compared with the results of other tests. This is determined by cutting a small piece from the uninjured portion of the test piece and weighing before and after thorough drying. The difference in weight divided by the dry weight and multiplied by 100 gives the percentage of moisture.

237. Strength of timber. The strength of timber depends upon the amount of heartwood or sapwood, knots (sound or loose), wind shakes and checks, cracks, or any defect that breaks the continuity of the fiber. In general, the strength of timber is indicated by its weight, the heaviest timbers being the strongest. Timber is strongest along the grain both in tension and compression, as will be seen in what follows.

It has been found that values obtained for the strength of timber by testing small, carefully selected test pieces are much higher than those obtained by testing large commercial timbers. This is what
might be expected, since the larger commercial pieces contain knots and other defects not found in the selected test pieces. It has been found also that the place and conditions of growth, time of felling, method and time of seasoning, and many other factors have each some effect upon the strength of timber. Since the weight of timber is an indication of its strength, some idea of the relative strength of the more common species may be obtained by referring to the table given below.*

238. Compression tests. Compression tests are made on short blocks and long columns. For the short-block test the piece is placed in an ordinary testing machine between the moving head and the platform.

*Bureau of Forestry, Bulletin No. 1 D, "Timber."
with its ends as nearly parallel as possible, and the compression is measured by an ordinary compressometer, or similar instrument for measuring the lowering of the moving head. To provide for the nonparallelism of the ends, it is well to use a spherical bearing for one of the bearing ends. This will insure the proper "lining up" of the specimen so that the compression will be along the grain.

A strain diagram may be drawn by plotting loads in lb./in.\(^2\) as ordinates and the corresponding relative compressions as abscissas. The elastic limit, modulus of elasticity, modulus of resilience, and maximum strength may then be obtained from the diagram in the usual manner. Failure is either due to a splitting of the specimen or to a shearing off at an angle of about 30\(^\circ\) to the horizontal (Fig. 163). The latter is the characteristic failure for green timber.

The tests on long columns are made in much the same way as the tests on short blocks. Provision is made for fixing the ends of the columns so as to give the standard end conditions, namely, square ends, round ends, pin and square ends, etc. In either case sufficient data is taken to get a load-deflection curve by measuring the deflections at the center corresponding to selected load increments. These deflections are usually measured in two directions at right angles to each other.*

**Problem 187.** Fig. 164 represents the results of compression tests of pine, poplar, and oak, plotted with loads in pounds as ordinates and compression in inches as abscissas. The blocks were all 7 in. high, with an area of cross section as follows: pine, 2 in. \(\times\) 1.48 in.; poplar, 2 in. \(\times\) 1.48 in.; oak, 2 in. \(\times\) 1.47 in. Redraw the curves, plotting the loads in lb./in.\(^2\) as ordinates and the corresponding unit compressions in inches as abscissas. Determine for each material the elastic limit, the modulus of elasticity, and the modulus of elastic resilience. Also compare the results obtained with the results reported for these materials in compression in the following tables.

*For a report of the tests that have been made on full-sized timber columns the student is referred to Lanza's *Applied Mechanics*. 
239. Flexure tests. Flexure tests are usually made by supporting a rectangular piece at both ends and loading it in the middle, care being taken to guard against local failure at the supports and at the point of application of the load. This local failure may be prevented by inserting some kind of metal plate between the beam and the knife-edge. The deflections of the beam for specified loads are measured by means of a deflectometer, usually measuring to .01 in. or .001 in. From the data obtained from a test, a strain diagram may be drawn by plotting loads in pounds as ordinates and deflections in inches as abscissas. The fiber stress for any load within the elastic limit is determined, for central loading, from the formula

\[ p = \frac{Ple}{4I} \]

and the modulus of elasticity from the formula (Article 66)

\[ E = \frac{Pl^2}{48IDl} \]

The formulas used to determine the fiber stress in the case of the flexure of beams \( \left( \frac{P}{e} = M_{\text{max}} \right) \) are true only within the elastic limit of the material. They are used, however, to determine the fiber stress beyond the elastic limit, although they are only approximately true beyond this limit. The value of the fiber stress at rupture as determined by the formula is usually designated as the modulus of rupture (Article 65); it is expressed in lb./in.².

On account of the peculiar structure of timber the character of the fracture due to a failure in flexure is rather difficult to predict. In case the specimen is free from knots and the grain is parallel to the length of the piece, failure from concentrated central loading is likely to take place either on the tension or the compression side, or both. It may happen, however, even in the case of such a perfect specimen as indicated, that failure will be due to horizontal shear. In such cases shearing takes place along the spring growth of one of the annual rings. This may have been weakened previously by wind shakes.

If part of the beam is sapwood and part heartwood, the fracture will be influenced thereby, due to the difference in the strength of the two portions. A cross grain may cause a failure due to splitting.
TIMBER

STRAIN DIAGRAM

COMPRESSION TEST OF PINE, POPLAR, AND OAK

Fig. 164
Knots of any kind near the central portion of the beam may determine the fracture and cause the beam to break off almost squarely. No law has yet been determined which will give the effect of knots of various sizes on the strength of timber.

Some characteristic failures in flexure are shown in Fig. 165. The lower beam shows a normal failure on the tension side. The two upper beams show the fracture of a somewhat more brittle material, the fracture being influenced by the presence of knots. The upper beam also shows a compression failure.

**Problem 188.** A rectangular pine beam, width 1.48 in., height 1.99 in., and span 30 in., was tested in flexure by being supported at both ends and loaded in the middle, and the following data obtained. Draw the strain diagram, plotting loads in pounds as ordinates and deflection in inches as abscissas. Locate the elastic limit and compute the fiber stress on the outer fiber at the elastic limit. Also compute the modulus of rupture, the modulus of elasticity, and the modulus of elastic resilience.

**240. Shearing tests.** The shearing strength of timber parallel to the grain is usually measured by finding the force necessary to cause a small projecting block of the material to shear off along the grain.
In this case the line of action of the force is parallel to the grain. The intensity of stress is obtained by dividing the force by the area of the sheared surface.

241. Indentation tests. Indentation tests are intended to show the crushing strength of timber perpendicular to the grain. A rectangular piece of timber is usually chosen, and a metal block whose width equals the width of the specimen is pressed into it by an ordinary testing machine. Convenient load increments are taken, and these, together with the corresponding compressions, give sufficient data for a load compression curve from which the elastic properties may be determined. Fig. 166 illustrates a specimen that has been tested in compression perpendicular to the grain.

242. Tension tests. Tension tests of timber are seldom made on account of the difficulty of obtaining satisfactory test pieces. The specimens to be tested must be much larger at the ends than in the middle in order to provide for attachment in the heads of the testing machine, and for this reason the piece is likely to fail by the shearing off of the enlarged ends, or by the pulling out of the fastenings. This test, therefore, is little used, the flexure test being relied upon to furnish information regarding the tensile strength of timber.

243. European tests of timber. As early as the middle of the eighteenth century tests to determine the strength of timber were made in France. This work was done for the most part from a scientific standpoint. The most important European tests were carried out by Bauschinger in his laboratory at Munich, from 1883 to 1887. The object of these tests was to determine the effect of the time of felling and conditions of growth upon the strength of Scotch pine and spruce. From these tests Bauschinger drew the following conclusions.

1. Stems of spruce or pine which are of the same age at equal diameters, and in which the rate of growth is about equal, have the same mechanical properties (when reduced to the same moisture contents), irrespective of local conditions of growth.
2. Stems of spruce or pine which are felled in winter have, when tested two or three months after the felling, about 25 per cent greater strength than those felled in summer, other conditions being the same.

He notes, however, that later tests may change these conclusions somewhat.

244. Tests made for the tenth census. In the United States, tests were made for the tenth census on four hundred and twelve species of timber. The test specimens were all small, selected pieces, 1.57 in. × 1.57 in. in cross section, and 43 in. long, and were seasoned in a dry, cool building for two years. On account of the number of species tested the results obtained are not conclusive, but should be taken as indicating the probable values for the strength of the timbers tested. On page 290 is given a table of the averages for some of the species tested. Since the test pieces were all small, selected specimens, the results are probably higher than would have been obtained from larger commercial specimens.

In the transverse tests the specimens were supported at both ends and loaded in the middle, the span being 39.37 in. The compression tests parallel to the grain were made on pieces 1.57 in. × 1.57 in. in cross section, and 12.6 in. long. Indentation tests were made on pieces 1.57 in. × 1.57 in. in cross section and 6.3 in. long. The test pieces in the latter case rested upon the platform of the testing machine, and the tests were made by crushing perpendicular to the grain with a plate 1.57 in. × 1.57 in. in size, by lowering the moving head of the machine.

245. Tests made by the Bureau of Forestry. The most extensive series of timber tests that has ever been undertaken has been begun by the United States Department of Agriculture under the direction of the Bureau of Forestry. These tests were begun in 1891, under the direction of Professor J. B. Johnson, at St. Louis. Thirty-two species were tested and 45,000 tests were made. The material was selected with special reference to the conditions under which the trees were grown, and the test pieces were small, selected specimens. The table on page 292 gives the average results of some of the tests.*

In the table the results have been reduced to an amount of moisture equivalent to 12 per cent of the dry weight.

A comparison of this table with that of the tenth census shows as close an agreement in most cases as might be reasonably expected when the variability of timber is considered, and serves to extend and verify the results of the previous work.

The effect of the presence of moisture on the strength of timber was also investigated when these tests were made by testing some of
the foregoing species endwise in compression while green. The following table gives the results of these tests in lb./in.\(^2\). The pieces contained over 40 per cent of moisture. A comparison of the results obtained from these tests with those reported in the preceding table shows that the compressive strength has been diminished from 50 to 75 per cent by the presence of the given percentage of moisture.

Certain special tests were also made to determine:

(a) The effect of bleeding (tapping for turpentine) on long-leaf pine.
(b) Influence of size on transverse strength of beams.
(c) Influence of size on compressive strength.
(d) The effect of hot-air treatment in dry kilns on strength.

The results obtained from these tests indicated:

(a) That bleeding does not affect the strength.
That large, sound beams may be as strong as small ones cut from the same piece; that is, large beams may show the same fiber stress as small ones.

That large, sound pieces in compression may be as strong as small ones cut from the same piece; that is, the intensity of compressive stress may be the same.

That there were no detrimental effects.

The results of the tests made by the Bureau of Forestry, as outlined in this article, should not be taken as conclusive, since not a sufficient number of tests were made to establish values. The pieces were in most cases small, and specially selected, and the results are of more value from a scientific than from a commercial standpoint, since the lumber of commerce contains knots, wind shakes, and other defects that lessen its strength.

246. Recent work of the Bureau of Forestry. At the present time (1906) the Bureau of Forestry, under the direction of Professor W. K. Hatt of Purdue University, is carrying out tests designed to give valuable information to engineers, architects, lumbermen, and others on the strength of commercial lumber. The following is an outline of the tests now under way.*

1. Tests of the mechanical and physical properties of timber in forms found on the market. The material will be of the same size and grade as commercial products. The purpose is to determine moduli for design; to determine the value of woods now considered inferior; to determine the liability to knots and the reducing factors due to these; to arrange a table of standard weights, and rules of inspection and grading; and partly to compare the properties of species from different regions.

2. The effect of rate of application of load, including impact tests.

3. The effect of moisture.

4. The effect of preservatives.

5. The effect of methods of seasoning.

6. The effect of fire retardants.

The test pieces for 1 are large commercial pieces in which knots and other defects occur, as they do in the structural timbers used by engineers.

A summary of some of the cross-bending tests of 1, already made, is given in the following table.

The grades **selects**, **merchantable**, and **seconds**, referred to in the table, are those from the Pacific Coast standard grading rules for Douglas Fir for 1900. A copy of these rules is here given.

**Merchantable.** This grade shall consist of sound, strong lumber, free from shakes, large, loose, or rotten knots, and defects that materially impair its strength; it shall be well manufactured and suitable for good substantial constructional purposes.

*Will allow* occasional variations in sawing or occasional scant thicknesses, sound knots, pitch seams, and sap on corners, one third the width and one half the thickness. Defects in all cases to be considered in connection with the size of the piece and its general quality.

**Seconds.** This grade shall consist of lumber having defects which exclude it from grading as merchantable.

*Will allow* knots and defects which render it unfit for good substantial constructional purposes, but suitable for an inferior class of work.

**Selects.** Shall be sound, strong lumber, good grain, well sawn.

*Will allow*, in sizes 6 by 6 and less, knots not to exceed 1 in. in diameter; sap on corners one fourth the width and one half the thickness; small pitch seams when not exceeding 6 in. in length.
## COMPARATIVE STRENGTH OF LARGE AND SMALL SPECIMENS

(For other work done by the Bureau of Forestry the student is referred to the bulletins giving the results of timber tests)

STRENGTH OF MATERIALS
In sizes over 6 by 6, knots not to exceed 2 in. in diameter, varying according to the size of the piece; sap on corners not to exceed 3 in. on both face and edge; pitch seams not to exceed 8 in. in length.

Defects in all cases to be considered in connection with the size of the piece and its general quality.

The cross-bending tests of 1 were made upon large specimens ranging in size from 6 in. x 8 in. x 7 ft., to 8 in. x 16 in. x 16 ft. The table shows that the modulus of rupture is less for the poorer grades of timber than for the selects, showing the effect of knots and other imperfections. The modulus of elasticity, indicating the stiffness, is less for the poorer grades, except in the case of shipment B of red fir.

The same report also makes a comparison of the strength of large sticks and small sticks, both in cross bending and in compression parallel to the fiber.

The table on page 296 gives average values obtained from this report, and indicates that the strength of the small sticks is, in nearly every case, greater than the strength of the large sticks. The modulus of elasticity is less for the small sticks than for the large ones, indicating a greater stiffness for the latter.
CHAPTER XVII

ROPE, WIRE, AND BELTING

247. Wire. Wire is made from a steel or iron rod by pulling it through a hole, or die, of smaller diameter than the rod. This is called drawing, and is done while the metal is cold. It is known as wet drawing when the metal is lubricated, and as dry drawing when no lubricant is used. The drawings are made with a smaller sized die each time, until the desired diameter of wire is obtained. Cold drawing of steel and iron raises the elastic limit and ultimate strength of the metal and decreases its ductility. It is made ductile again by annealing, and is finished by giving it the proper temper consistent with the desired use.

The Mining Journal for 1896 gives the following values for the strength of wire.

<table>
<thead>
<tr>
<th>Material</th>
<th>lb./in.²</th>
</tr>
</thead>
<tbody>
<tr>
<td>Iron wire</td>
<td>80,000</td>
</tr>
<tr>
<td>Bessemer steel wire</td>
<td>90,000</td>
</tr>
<tr>
<td>Crucible cast steel</td>
<td>240,000</td>
</tr>
<tr>
<td>Mild open-hearth steel</td>
<td>130,000</td>
</tr>
</tbody>
</table>

Piano wire varies in strength from 300,000 lb./in.² to 400,000 lb./in.².

248. Wire rope. Wire rope is made by twisting a number of steel or iron wires into a strand, and then twisting a number of these strands about one of the strands, or about a hemp, manila, jute, or cotton strand. The exact composition of the cable or wire rope will depend upon the service for which it is designed. The hemp core gives added pliability to the cable, and acts as a means of lubricating the strands and wires; this reduces the internal friction in the cable, and adds much to its life in case it is used where pliability is required, as in running over sheaves. Fig. 167 is an illustration of the cross section of a cable in which the separate strands each have a hemp core. Such a cable can be used where great pliability is required. Fig. 168 shows a cross section of a cable with
a single hemp core at the center, and Fig. 169 shows a cross section of a cable in which the center is a wire strand similar to those used on the outside. A cable of the latter type can only be used where little bending is required, as in the case of suspension bridges. The strands are twisted about the central core either to the right or left. When twisted to the left the rope is designated as left lay, and when twisted to the right as right lay. The twist is long or short, depending upon the requirements of service. The shorter the twist the more flexible the rope, and the longer the twist the less flexible.

249. Testing of rope wire and belting. These materials are usually tested in tension. This may be done in an ordinary testing machine, providing the proper means are used for holding the specimen. A type of wire-testing machine is shown in Fig. 170. One end of the wire is clamped to the movable head and the other to the stationary head, which is provided with a spring balance for registering the pull. Many other types of wire-testing machines are in use, some of them being arranged to make torsion tests. Many special machines are also made for testing rope and belting.

Since a wire rope is a built-up structure, made of twisted strands, it is not to be expected that it will exhibit such well-defined elastic properties as a single wire tested separately. This is due to the fact that as the tension is increased each strand, which was originally in the form of a helix of a certain pitch, becomes somewhat straightened and takes the form of a helix of a greater pitch. On account of the twisted condition of the wires in the strands, they do not all carry the same load, and therefore do not all reach their elastic limit at the same time. We find, consequently, upon testing a wire rope, that it has no well-defined elastic limit.

The individual wires of which the rope is made show a very high tensile strength and elastic limit, but exhibit no yield point, as the process of drawing seems to destroy the properties of the material that give the yield-point phenomena. The modulus of elasticity is not changed appreciably by the process of drawing.
Problem 189. A piece of steel music wire was tested in tension and the following data obtained. Draw the strain diagram, using loads in lb./in.² as ordinates and unit elongations as abscissas, and find the elastic limit, the modulus of elasticity, and the modulus of elastic resilience. The wire was No. 25 gauge; diameter before test 0.0577 in., and sectional area 0.002615 sq. in. It was tested on a gauge length of 6 in. The sectional area at the point of fracture after test was 0.00132 sq. in. Compute the percentage of reduction of cross section.

In the above table the actual sectional area of the wire in the rope is given, and the tensile strength in lb./in.\(^2\) has been computed by dividing the total load by this area. An examination of the table giving the strength of the individual wires shows that the intensity of stress is greater in the case of the individual wires than in the wire rope; that is to say, the structure of the rope causes the wires to lose some of their efficiency.

The table at the bottom of page 301 gives the strength of iron and cast-steel wire rope as given by John A. Roebling's Sons. The size of a new Manila rope of the same strength is also given for comparison.

### STRENGTH OF WIRE ROPE MADE FROM CAST STEEL AS GIVEN BY JOHN A. ROEBLING

(Rope composed of six strands and a hemp center, seven or nineteen wires in each strand)

**Problem 190.** A wire cable of the following dimensions and composition was tested, and its maximum load found to be 5080 lb. Diameter of cable, 0.33 in.; six strands of eleven wires each; sectional area of wires, 0.025 in.². A test of the individual wires showed an average strength of 225,600 lb./in.². Find the loss of strength due to the twisting of the wires to form the cable, assuming that all the wires have the average strength given above.

**251. Strength of Manila rope.** The following table gives the strength of Manila and sisal rope as computed from tests made by the Watertown Arsenal.* The load in lb./in.² is given in each case. This has been computed by considering the cross section of the rope as the area of a circle of the same diameter. It will be seen from the table that the stress for the smaller ropes was 15,000 lb./in.², while for the larger ropes it was only about 7000 lb./in.². This difference is due in part to the greater length of yarn used in the smaller rope. Manila rope has about two thirds the strength of good Russian hemp rope.† The United States Navy test allows 1700 lb./in.² as the working strength of a 1.75-in. hemp rope.

* Watertown Arsenal Report, 1897. † Thurston, Materials of Construction.

</table>
252. Strength of leather and rubber belting. Leather belts are made from tanned oxhide. That portion of the hide that originally covered the back gives the best leather for this purpose. The "flesh side," or side originally next to the animal, wears better when placed in contact with the pulley, while the outside gives the greater adhesion when placed in contact with the pulley.

Single belts are made from one thickness of leather, the desired length being obtained by cementing or splicing the short lengths cut from the hide. Double belts are made by cementing two thicknesses of the leather together. The strength of good leather varies from 600 to 700 lb. per inch of width, and from one half to two thirds as much when spliced. The following table gives the strength of cemented belt laps as determined by the Watertown Arsenal.* A complete series of tests on belt lacings is also reported in the same volume, and the student is referred to this report for the results. The allowable stress on a single belt is from 250 to 300 lb. per inch of width.

theorem of three moments, 80.
vertical shear, 47, 56, 58, 60.
work of deformation, 83.
Bearing power of soils, 195.
Beech, strength of, 290.
Behavior of iron and steel in tension, 222.
Belting, strength of, 304, 305.
Bending and torsion combined, 32.
Bending, cold, 231.
Bending moment defined, 36.
Bending moment and shear; relation between, 53.
Bending moment, maximum, 48, 50, 51, 52, 53.
Bernoulli's assumption, 34.
Bessemer process, steel manufacture, 239.
Black walnut, strength of, 290.
Box elder, strength of, 290.
Brick, absorption of, 281.
compression of, 276, 277.
flexure of, 280.
manufacture of, 276.
modulus of elasticity of, 278.
rattler test of, 280.
Brick piers, strength of, 277.
Briquettes, cement, 250.
compression of halves of, 252.
molding and care of, 251.
tensile strength of, 252.
Building blocks, concrete, 262.
Bureau of Forestry timber tests, 291, 292, 294.
Bursting pressure of thick cylinder, 133.

Cantilever, 55.
Carbon in cast iron, 232.
in steel, 239.
Castiglano's theorem, 93.
application to continuous beams, 94.
Cast iron, manufacture and general properties of, 231.
compression of, 234.
elasticity of, 234.
flexure of, 234.
impurities in, 232.
malleable, 237.
modulus of rupture of, 238.
shear of, 234.
specifications for, 237.
tensile strength of, 232, 238.

Cast-iron columns, 230.
Castings, malleable, 237.

Cedar, strength of, 290, 292, 293.

Cement, 247.
compression tests of, 252, 253.
specifications for, 253.
test of fineness, 249.
test of soundness, 248.
test of tensile strength, 250, 252.
test of time of setting, 240, 250.

Cinder concrete, 260.
Circular plates, 135, 137.
Circular shafts in torsion, 112, 113, 114.
Classification of materials, 9.
Coefficient of cubical expansion, 29.
Coefficient of elasticity. See Modulus of elasticity.
Coefficient of linear expansion, 12.
Cold bending test, 231.
Column footings, 203.

Columns, beams of considerable depth, 111.
cast-iron, 236.

Cooper's modification of Johnson's straight-line formula, 110.
one or both ends fixed, 100.
Euler's formula, 100, 101.
Gordon's formula, 104.

Johnson's parabolic formula, 100, 107.
modification of Euler's formula, 103.
nature of compressive stress, 98.
Rankine's formula, 104, 105.

Combined bending and torsion, 32, 115.

Common theory of flexure, 34.
Compression, defined, 2.
brick in, 276, 277, 278.
brick piers in, 277.
cast iron in, 236.
cement in, 252, 253.
concrete in, 258, 259, 260.
stone in, 273, 274.
tests, 221.
timber in, 284, 290, 292, 293, 296.

Compressive strength, average values, 19.
Concrete building blocks, 262.

Concrete. See Masonry arches.
mixing, 257.
modulus of elasticity of, 259.
reinforced. See Reinforced concrete.
tests of, 255, 256, 257, 258, 259, 260.

Concrete-steel plates, 143.
Consequence of Bernoulli's assumption, 35.

Continuous beams. See Beams.
Contraction of area, 14, 223.
Core section, 65, 66, 67.
Cottonwood, strength of, 290.
Cross-bending. See Flexure.
Crushing. See Compression.
Curvature due to bending moment, 34.
Curve, elastic. See Elastic curve.
Curved pieces, 145.

Cylinders and spheres, thin, 122.
Cylinders, thin:
elastic curve for, 125.
hoop tension in, 123.
longitudinal stress in, 123.

Cylinders, thick, 130.
bursting pressure, 133.
Lamé's formulas, 130.
made of concentric tubes, 134.
maximum stress in, 132, 133.

Cypress, strength of, 292, 293.

Dangerous section, 49.
Deflection of beams. See Beams.
INDEX

Deflection of columns. See Columns.
Deformation defined, 2, 4.
Designing of arches, 179.
Designing of beams, 64.
Diagram, bending moment and shear, 49.
Douglas spruce, strength of, 292.
